Although 25 placebo-controlled drug trials and 13 trials comparing two or more active treatments with drugs have been conducted, there is no FDA approved drug for the treatment of BED. Of the selective serotonin reuptake inhibitors (SSRIs) studied, only citalopram (183), escitalopram (184), and sertraline (185) were associated with a greater reduction of binge frequency reduction and symptom severity. The tricyclic antidepressants, desipramine and imipramine, were greater than placebo for reducing binge eating, weight, and depression in those with BED (186).

The antiepileptics, topiramate and zonisamide, have been the most effective drugs for reducing binge eating frequency and weight (187,188). The selective norepinephrine reuptake inhibitor, atomoxetine, reduced binge frequency and weight more than placebo in one study (189). Several trials of lisdexamfetamine dimesylate, a drug used to treat ADHD, provided evidence that this drug was also effective for reducing binge frequency and weight (190). Orlistat, an anti-obesity drug, when combined with CBT was more effective than CBT for reducing binge eating (191). Acamprosate, a mixed GABA agonist/glutamate antagonist, had a greater reduction in binge days per week compared with placebo (192) but no difference in achieving abstinence.

At present evidence-based data indicate cognitive behavioral therapy should be the first-line treatment for BED. Most drug studies for BED have had limited follow-up periods and have not reported on remission of binge eating.

RESEARCH DIRECTIONS

Many questions need to be answered in order to create effective prevention and treatment programs for eating disorders. It is necessary to learn how an individual's genotype and environment interact to create, maintain, and recover from an eating disorder. Advancing techniques in genetics and neuroimaging are producing information on normal brain developmental changes in adolescence, the time period most eating disorders develop. Knowledge is needed on the role of genetic, environmental factors (life stress), weight loss, food restriction (starvation), and other core eating disorder behaviors (purging) in mediating the effects of brain developmental trajectories. Probing how patterns of neuropsychological assets and deficits (perfectionism, anxiety, negative mood states) may influence the development of an eating disorder can be conducted via various neuroimaging techniques. Although the above personality traits may influence susceptibility to cultural messages, peer influences, and internalization of the thin ideal, the mechanism in the brain by which this is accomplished is unknown.

Information on how dysregulation within and/or between limbic and executive corticostriatal circuitry may contribute to inhibition and self-control would be useful for treatment interventions in anorexia and BN. Neuroimaging studies of alterations of structural and functional connectivity are needed to identify specific brain circuits

involved in the core eating disorder symptomatology.

Prospective longitudinal studies are needed to observe how brain alterations are related to risk, causing, maintaining, or the consequence of an eating disorder. Current research indicates eating disorders will have a polygenic etiology. Genes identified by epigenetic studies are likely to have a significant influence in the development of eating disorders and need more extensive investigation.

Improving treatment strategies will come about with the integration of emerging data from multiple sources. Problems of high treatment dropout rates, motivation for treatment, individualized treatment, insurance coverage, early diagnosis to facilitate early treatment, dissemination of effective treatment knowledge, and support for innovative treatment approaches and innovative research will continue to be a challenge in the next decade.

CHAPTER 5.7.2 ■ PICA, RUMINATION DISORDER, AND AVOIDANT/RESTRICTIVE FOOD INTAKE DISORDER

KATHRYN A. CONIGLIO AND JENNIFER J. THOMAS

INTRODUCTION

Although anorexia nervosa (AN), bulimia nervosa (BN), and binge eating disorder (BED) get considerable attention in research and clinical practice, other lesser known feeding and eating disorders exist. *The Diagnostic and Statistical Manual*, fifth edition (DSM-5) also describes pica, rumination disorder (RD), and avoidant/restrictive food intake disorder (ARFID). Earlier descriptions of both pica and RD were included in DSM-IV. ARFID, however, is a revised version of DSM-IV feeding disorder of infancy and early childhood, meant to capture inadequate volume or variety of food intake throughout the lifespan. While none of these disorders are characterized by the distorted body image and overvaluation of shape and weight that characterize AN and BN, all three can cause significant medical and psychological impairment. Although less is known about these disorders, clinicians should be familiar with their presentations to aid in detection, and their more prominent placement in DSM-5 has inspired new research on their optimal assessment and treatment.

PICA

Clinical Definition

Four diagnostic criteria characterize pica (1). The first and *sine qua non* is persistent consumption of nonfood, nonnutritive substances for 1 month or more. Unlike individuals with AN or BN, those with pica do not show aversion to food in general and may consume food in addition to nonfood substances. Pica substances include chalk, coal, ash, clay, dirt, laundry starch, other powdery substances such as talcum powder or makeup, and feces (2). Previous versions of DSM did not include "nonfood" as a qualifier for substances consumed; this term was added in DSM-5 to exclude individuals who consume items—such as ice, raw pasta, or artificial sweetener—that, despite having minimal nutritional value, are still considered food (3).

The second criterion describes the consumption of nonfood, nonnutritive substances as inappropriate given the individual's developmental level (1). For example, a teething infant who eats or sucks on nonnutritive substances should not be

diagnosed with pica. For this reason, an age of 2 years is the suggested minimum for a pica diagnosis.

The third criterion for pica is that the consumption of nonfood substances is not attributable to a socially or culturally normative behavior (1). In some cultures, dirt, clay, or other nonfood, nonnutritive substances are consumed for their believed medicinal or spiritual benefits (2). For example, geophagia, or the consumption of earth, has been documented as early as 460 BC in ancient Greece and Rome (4). Geophagia has since been observed, primarily among women from communities in sub-Saharan Africa, for believed benefits of skin softening and increased fertility (5). Thus, among communities where geophagia or similar practices are culturally accepted, a diagnosis of pica would not be warranted.

The fourth criterion for pica states that, in the presence of other comorbid medical complications, pica should only be diagnosed if the consumption of nonfood, nonnutritive substances is serious enough to warrant additional clinical attention (1). Likewise, a diagnosis of pica is not warranted when a person consumes nonfood, nonnutritive substances for perceived appetite suppression effects, as a method of nonsuicidal self-injury, or because the person feels compelled to do so as a result of a psychotic disorder, like schizophrenia.

Of note, pregnancy is included as an exemptive medical condition in DSM-5, unless the consumption of nonfood substances is severe enough to warrant additional clinical attention (1). This is partly because pica-like ingestion of nonfood, nonnutritive substances has been associated with iron and zinc deficiencies, which can be present in pregnant women (6). Micronutrients such as iron and zinc are commonly found in soil, clay, and other earthen materials that people who have pica may consume. Available data provide conflicting evidence as to whether pica is correlated with micronutrient deficiencies (7,8). Further studies are needed to examine the strength of this relationship and its implications for the etiology and treatment of pica.

Prevalence of pica are largely unknown and vary widely. A recent study by Delaney et al. (9) found that pica prevalence was 1.3% among adolescent and young adult females in residential eating disorder treatment in the United States, whereas another study found a 74.4% prevalence in a sample of mixed sex schoolchildren in Lusaka, Zambia (10). Prevalence estimates for pica vary widely due in part to differing definitions across studies (e.g., inclusion vs. exclusion of ice as a pica substance) and changing definitions of pica from DSM-IV to DSM-5. For example, a recent review of four prevalence studies of pica among “institutionalized individuals with intellectual disability” (p. 206) found that prevalence ranged from 9.2% to 25.8% (11). However, the latter figure came from a study that used a broader definition of pica that included some potentially nutritive substances (e.g., coffee grounds, excessive water consumption) (12) that would not meet the first DSM-5 criterion.

Pica is often associated with intellectual developmental disorders and developmental disabilities (1). Pica also often co-occurs with obsessive-compulsive spectrum disorders such as trichotillomania, in which individuals may consume the hair they have pulled. Case studies also indicate that individuals with OCD may engage in consuming nonfood, nonnutritive substances, such as cigarettes or paint chips, as part of compulsion rituals (13).

Medical Complications

Individuals with pica can experience from potentially fatal medical consequences, depending on the level of toxicity of the substance ingested. Complications of pica can include injuries to the mouth and gastrointestinal (GI) tract, intestinal blockages, lead poisoning, constipation, parasites, and infections (2,14). In a retrospective medical record review of 35 individuals with pica described as "mentally handicapped" (p. 552) and undergoing surgery to remove foreign bodies from the GI tract in an inpatient community hospital, 11% eventually died from surgical complications directly related to pica (15).

Iron-deficiency anemia (IDA) is often associated with pica, although it is unclear whether IDA is a consequence or a cause. Some research has suggested that clay and dirt can block absorption of iron in the bloodstream, thus leading to iron deficiency (7), while others have suggested that individuals may crave iron-containing substances (e.g., dirt or soil) in order to correct a pre-existing iron deficiency (2).

Pica can impair psychosocial functioning as well. Many people with pica do not seek treatment, citing embarrassment and shame as primary deterrents (9,16). Purchasing and consuming nonfood substances are typically done in secret. One case report documented that an individual with pica often resisted the urge to engage in the eating behavior, only to find that the urge did not relent until she consumed her preferred pica substance (16).

Etiology

Although DSM-IV categorized pica under Disorders Usually First Diagnosed in Infancy, Childhood, or Adolescence; DSM-5 recategorized pica under Feeding and Eating Disorders in recognition that pica can occur across the lifespan. However, pica typically onsets in childhood (17). Multiple theories of pica etiology have been posited, from both anthropologic and behavioral standpoints. Young (2) suggested three main etiologic theories: pica is an adaptive response during times of food shortage/famine; pica represents a pre-existing micronutrient deficiency; and pica acts as a natural protection against toxins and illness. While these theories may hold true for some individuals with pica, they do not represent a comprehensive etiologic framework, and are largely unsupported by empirical work. In contrast, behavioral

theorists hypothesize that pica may be the result of a learned behavior from environments with little social interaction (18). Indeed, in children, pica has specifically been associated with environments of parental neglect (19). The link between diminished or inappropriate social interaction, be it a cause or consequence of pica, has inspired behavioral techniques to target pica behaviors (20,23).

Assessment

Pica is underreported in clinical settings, likely due to individuals not spontaneously volunteering symptoms, and clinicians not inquiring (9). Individuals with pica may conceal their consumption of nonfood items for fear of being viewed as financially poor or intellectually disabled (2,9). Indeed, historically, pica was more heavily documented among people with low socioeconomic status (e.g., enslaved and/or indigenous populations) or intellectual disability (2). For these reasons, individuals with pica may initially present with physical ailments such as stomach cramping or injuries to the GI tract. Thorough physical examinations (including x-ray or MRI if needed), blood tests, and nutritional consultation may be helpful to rule out medical complications in instances where pica is suspected (17).

Clinically, the individual should be questioned about the types of items that he or she consumes that aren't "normal food." This can be done through unstructured clinical interviewing based upon DSM-5 criteria, or by using a standardized assessment. The Eating Disorder Assessment for DSM-5 (EDA-5) (21) is a brief "app"-based interview with good psychometric properties that clinicians or researchers can implement to ascertain the presence or absence of DSM-5 feeding and eating disorders including pica. For a more detailed assessment, the Pica, ARFID, and Rumination Disorder Interview (PARDI) is a semi-structured interview that can be used clinically to diagnose pica and assess severity and related impairment among individuals ages 2 and older (22). For respondents under age 13, a parent/carer version of the interview can be implemented to obtain collateral information to supplement self-report. The PARDI is the only standardized clinical assessment tool that provides a continuous measure of pica severity, and is currently undergoing pilot testing in a multisite validation trial.

Treatment

At present, no evidence-based treatment protocol exists for pica specifically. However, case reports have described behavioral techniques that have been effective in reducing the severity and overall occurrence of pica behaviors. Functional analyses are useful prior to starting treatment, as the function that pica behaviors serve likely vary by individual (23). Common to most individuals, however, is that pica is a stimulating behavior that is maintained through positive automatic

reinforcement. Applied Behavioral Analysis (ABA) has been effective in treating pica, specifically among children with developmental disorders. In a qualitative review of pica treatment techniques, Matson et al. (24) found that successful components of ABA to treat pica include both "punishment procedures" (p. 2565) and "positive procedures" (p. 2568). Punishment procedures can include incorporating taste aversion techniques (such as pairing lemon juice or aromatic ammonia [e.g., smelling salts] with the pica substance), and overcorrection following the behavior (i.e., encouraging an individual who eats cigarettes to thoroughly wash his or her teeth and clean up trash around him or her following the behavior). Positive procedures can include offering appropriate and preferred food substances and introducing novel and enriching elements to the environment (e.g., new types of play) to increase engagement in replacement behaviors (24).

RUMINATION DISORDER

Clinical Definition

RD is characterized in DSM-5 by persistent regurgitation of food for 1 month or more (1). Regurgitated food can be rechewed, reswallowed, or spit out. DSM-5 describes that this behavior typically occurs several times per week—often daily—though this is not a formal diagnostic criterion (1). In a study of clinical features in a pediatric sample of individuals with RD, 100% of the sample endorsed daily rumination, after almost every meal (25). It is important to note that rumination is different from vomiting; individuals with RD typically do not retch or feel nauseous when food is regurgitated, and often, the food is not acidic. For instance, a person with gastroesophageal reflux disease (GERD) who experiences frequent regurgitation as a result of reflux cannot be diagnosed with RD unless he or she also engages in persistent regurgitation outside of reflux episodes (1). Rather, rumination behaviors must occur independent of a medical condition that is better able to account for the behavior.

RD must also occur independently of other eating disorders, such as AN, BN, BED, or ARFID (1). While previous studies have shown that rumination behavior can co-occur with other eating disorders, a formal diagnosis of RD is inappropriate in these cases, according to DSM-5 (9). In cases of intellectual disability or other mental disorders, however, RD can be a comorbid diagnosis if the behaviors are severe enough to warrant additional clinical attention (1).

Prevalence of RD in the general population are unknown. One study in a residential eating disorder facility in the United States indicated that 7.4% of the (all-female) participants endorsed rumination behavior, but none received a formal diagnosis of RD due to DSM-5 trumping rules, which specify that RD cannot co-occur with another eating disorder (9). Just as with pica, RD is no longer a Feeding

Disorder of Infancy or Early Childhood; adults are able to receive this diagnosis under DSM-5 and adult cases have been documented in the literature (26,27). A recent prevalence study among male and female school-aged children (ages 10 to 16 years) in Sri Lanka found that 5.1% met criteria for rumination syndrome (RS) using Rome III criteria (28). Similar to DSM-5, Rome III criteria state that a diagnosis of RS should involve repeated, painless regurgitation of food. This regurgitation should occur shortly after a meal, not occur during sleep, and not involve retching (29). Unlike DSM-5, however, Rome III criteria need only be present once per week for 2 months. While DSM-5 does not include a definitive behavior frequency in RD criteria, it suggests this behavior will occur many times per week, perhaps even daily. Although methodologic differences make prevalence difficult to compare across studies, available data suggest that, like pica, RD is relatively rare in the general population.

Medical Complications

Although different from vomiting, the regurgitation of food in RD can yield medical consequences that are similar to those found in patients who frequently purge through vomiting. These can vary depending on severity and length of illness, and some can be quite serious. Electrolyte imbalances, dehydration, dental erosions, and weight loss are among the most clinically impairing complications (30).

RD can have a negative impact on social activities as well. Among pediatric patients with RD, 73% endorsed missing school or work due to associated symptoms of RD, such as abdominal pain or constipation (25). Some people with RD may attempt to conceal this behavior in social settings, due to shame or embarrassment (27).

Etiology

The etiology of RD is largely unknown, though it appears that rumination may function in infants and those with developmental disabilities as a self-soothing behavior (14). Clinically, patients endorse varying degrees of self-control over rumination behavior (31), yet behavioral theory posits that the physiologic mechanisms that allow one to ruminate are voluntary (32). Among individuals with RD, rumination may serve as a learned habit in response to external cues, including starting or ending a meal, or feelings of fullness while eating. Individuals may habitually, yet subconsciously, initiate rumination by contracting the abdominal wall and ruminating in a controlled fashion (32). Individuals with RD may be unaware that this behavior is a learned response. In such cases, developing insight into the individual's own role in maintaining the regurgitation behavior is often a key component of RD treatment.

Assessment

Patients with RD may not volunteer information to family, friends, or healthcare workers without prompting (27,30). To assess symptoms of RD, clinicians can use the EDA-5 (21) as a brief diagnostic measure, or the PARDI (22) to confer a diagnosis and also assess RD severity and associated clinical impairment. The clinician should be sure to differentiate the rumination behavior from food coming back up into the mouth due to vomiting or acid reflux. For the latter, the clinician can inquire if acid reflux medication helped to alleviate the rumination, as certain medications that are helpful to alleviate symptoms of GERD (i.e., reducing gastric secretion volume and acidity using proton pump inhibitors) (33) have not been studied for use with RD, and may exacerbate the problem.

Treatment

At present, no randomized controlled trials have identified preferred treatments for RD. However, several case reports have documented success in symptom alleviation using diaphragmatic breathing (26,34). Diaphragmatic breathing is a technique designed to relax the abdominal muscle contractions thought to initiate rumination behavior. Clinicians can demonstrate this technique during a routine medical visit or therapy session, as follows:

1. The therapist instructs the patient to place one hand on his or her chest and the other on his or her abdomen, and to inhale deeply. Typically, the patient will inhale through the chest, noticing the hand on his or her chest rise, while the hand on his or her abdomen barely moves.
2. The therapist then instructs the patient to inhale deeply through the abdomen only, attempting to keep the hand on his or her chest motionless. Breaths should be slow and last at least 3 seconds to inhale and 3 seconds to exhale. It may be appropriate, given the developmental level of the patient, to use imagery (e.g., a balloon being inflated and deflated) to help the patient achieve slow and deliberate breaths.
3. The therapist encourages the patient to practice diaphragmatic breathing during times when rumination behavior typically occurs. For some, this may occur partway through the meal, while for others it may occur post-prandially. Ultimately, with practice, the patient should engage in diaphragmatic breathing automatically during high-risk times, thus preventing the muscle contractions necessary to trigger regurgitation behavior.

AVOIDANT/RESTRICTIVE FOOD INTAKE DISORDER

Clinical Definition

ARFID is a revised and expanded DSM-5 version (1) of the disorder formerly known as DSM-IV Feeding or Eating Disorder of Infancy or Early Childhood (3). Specifically, DSM-5 includes ARFID to offer a specific diagnosis for individuals who obtain inadequate nutrition due to limiting the variety or volume of food consumed, whereas DSM-IV grouped these individuals heterogeneously along with other types of feeding and eating problems in youth. In addition, while DSM-IV stipulated that the disorder must onset before age 6, DSM-5 acknowledges that these presentations may onset later in life.

ARFID has four main DSM-5 diagnostic criteria, all of which must be fully met for diagnosis (1). The first is an eating disturbance that leads to significant weight loss, nutritional deficiency, dependence on a gastronomy (G) or nasogastric (NG) tube, and/or psychosocial impairment. Typically the individual eats a limited volume or variety of food due to (a) apparent lack of interest in eating or food, (b) avoidance based on the sensory characteristics of food, or (c) concern about aversive consequences of eating (e.g., vomiting or choking), but this is not an exhaustive list. Second, this disturbance in eating cannot be accounted for by lack of food availability. Third, the eating disturbance cannot occur solely during the course of AN or BN. Unlike individuals with AN or BN, those with ARFID do not restrict their food intake to influence their shape or weight, or to avoid an episode of overeating. Rather, restrictive eating is a consequence of lack of interest, sensory sensitivity, fear of aversive consequences, or another reason unrelated to shape or weight, as stated in the first criterion. Finally, the eating disturbance cannot be better explained by the presence of another physical or mental disorder, including food allergies and intolerances, GI disease, and neuromuscular disorders that may affect swallowing.

It is important to note that the inclusion of ARFID in DSM-5 is not meant to over-pathologize picky eating or to ascribe psychological dysfunction to individuals with medical problems that limit their diets. While selective eating patterns are relatively normative among young children, a study of over 2,000 pediatric patients ages 8 to 18 years seeking treatment for GI issues found that only 1.5% met criteria for ARFID (35). As outlined in criterion one, the eating disturbance must be accompanied by medical or psychosocial impairment that warrants additional clinical attention.

Medical Complications

Individuals with ARFID and related presentations can experience serious medical consequences. Those with avoidant/restrictive eating—especially those who present with the sensory phenotype—are less likely to eat fruits, vegetables, meats, or fish than nonselective eaters, citing bitter taste and aversive textures as key deterrents

(36,37). Additionally, some individuals with selective eating rely as dietary staples on high-carbohydrate foods that are not nutrient dense (38). This limited diet can lead to nutritional deficiencies that must be corrected either through supplementation, or in more extreme cases, enteral feeding (39). A recent case report of ARFID in an adolescent boy documented multiple nutritional deficiencies including low levels of vitamins A, D, E, K, B_{12}, and folate (40), resulting in macrocytic anemia, osteoporosis, and subacute combined degeneration (SCD) of the spinal cord.

In cases of extreme food restriction, the patient may be underweight. Indeed, in one retrospective study of outpatients receiving an initial evaluation at an eating disorder clinic, there was no significant difference in BMI between youth with ARFID versus those with AN (41). Approximately one-third of ARFID patients in an outpatient eating disorder clinic required medical hospital admission due to extreme low weight or unstable vital signs (41). In the same study, bone mineral density (BMD) scores were significantly lower among ARFID patients than among AN patients ($p < 0.001$), with 25% of ARFID patients showing scores in the osteoporotic range.

Comorbidity

ARFID is common among people with ASD; estimates of picky or selective eating are as high as 89% among children with ASD, though the rates of the full ARFID phenotype are unknown. In an eating disorder day treatment program, patients with ARFID showed significantly higher rates of comorbid anxiety disorders compared to those with AN (42). However, another study that also highlighted high rates of psychiatric comorbidity among individuals with ARFID found that, in contrast, those with ARFID were less likely than patients with AN to initiate psychopharmacological interventions (41). Therefore, it is important for clinicians to assess for any comorbid mood disorders and consider appropriate interventions.

Etiology

Multiple etiologies have been proposed for ARFID, though most are speculative, as ARFID is a burgeoning area of research. Behavioral theory, which has focused mainly on child presentations, posits that implicit associations form between the child’s behaviors around declining to eat (i.e., arguing, spitting out food) and the desired outcome (i.e., not having to eat the nonpreferred food). That this behavior is reinforced over time makes it difficult to extinguish. For traumatic experiences like vomiting or choking, implicit associations can be formed between the food and the aversive outcome. In extreme cases, this may be difficult to extinguish without clinical attention. In one study of 5,294 children ages 10 to 11 years, children who were identified by their mothers as being “choosy eaters” were more likely to be

“supertasters” (or, were more likely to have heightened taste sensitivity and experience taste sensation with more intensity than non-supertasters) than children who did not self-identify as being choosy eaters (43), highlighting the possibility that biologic differences in taste preferences contribute to ARFID etiology.

Assessment

Compared to those with AN and BN, individuals with ARFID are more likely to be younger and male (44). Three classic phenotypes are associated with ARFID; these correspond to the three examples provided by DSM-5 as follows:

(a) *ARFID with apparent lack of interest in eating or food*: Amit is an 11-year-old boy who often forgets to eat and requires prompting from his parents at mealtimes. When he does eat, he only tolerates small amounts before losing interest, often preferring to engage in other activities (e.g., talking, watching television) during mealtimes. He presents for treatment at the request of his pediatric gastroenterologist, who suggests the use of a feeding tube to ensure adequate caloric intake in the short-term.

(b) *ARFID with avoidance based on the sensory characteristics of food*: Shoshannah is a 28-year-old woman whose intense anxiety and panic around eating results in her eating the same foods every day (e.g., a specific brand and flavor of yogurt for breakfast, plain pasta without sauce for lunch, etc.). She often goes through phases in which she only eats one food (e.g., a specific type of chocolate bar) for several days, and then becomes surfeited of that food, selecting a new preferred food and reinitiating the cycle.

(c) *ARFID with concern about the aversive consequences of eating*: Sarah is a 6-year-old girl who choked on a piece of chicken, developed an intense fear of choking, and subsequently has eaten nothing at all for 6 consecutive days. Due to the extreme weight loss following the food restriction, Sarah requires a brief medical hospitalization for rehydration.

It is important to note that these phenotypes are neither mutually exclusive nor exhaustive. Patients may, and often do, exhibit features from more than one phenotype. At present, ARFID diagnoses do not require a phenotypic specifier in the way that a clinician may characterize AN with a restricting or binge/purge subtype. However, classification is important to assess in a clinical setting, as phenotypic presentations inform treatment modalities.

The PARDI can be used to diagnose ARFID and assess severity and clinical impairment (22). The PARDI includes subscales to establish the degree of similarity with each of the three classic ARFID presentations. Patients receive a score for each subscale, and can be matched with multiple phenotypes if applicable, which is consistent with the nature of ARFID presentations in a clinical setting. ARFID can also be assessed using the EDA-5 (21). As with pica and RD, the EDA-5 assesses

diagnostic criteria, but does not assess severity or impairment.

In clinical practice, it is important to ascertain the patient's current food intake on a typical day, including both the range of foods consumed as well as amounts, to fully assess the degree of potential nutritional deficiency (45). Individuals whose diets are quite limited in variety may benefit from blood tests to screen for nutritional deficiency, and those who are underweight may benefit from BMD scans. The clinician should also assess the patient's current weight and height, and, among children, whether there has been a recent drop in BMI centile. Failure to grow as expected for age is a potentially telling sign of inadequate nutrition (38).

Treatment

At present, there is no evidence-based treatment for ARFID, and available data on the effectiveness of specific interventions have focused largely on very young children. In clinical practice, approaches vary widely by discipline. In the absence of evidence for any specific treatment, we suggest that the intensity of any intervention be informed by the severity of nutritional compromise. For example, individuals who are very underweight may require inpatient hospitalization for refeeding, while those who are not underweight may benefit from outpatient care alone. Similarly, those with nutritional deficiencies may benefit from close medical monitoring and vitamin supplementation while they are working to expand their diets. In contrast, we suggest that within any given level of treatment intensity, specific therapeutic interventions be informed by the clinician's assessment of the presenting ARFID phenotype(s):

ARFID with apparent lack of interest in eating or food: Individuals who have diminished appetite or little interest in eating, like Amit, may present at low weight and require interventions designed to increase calorie intake. It is unclear whether evidence-based interventions for adolescent AN (e.g., family-based treatment in which parents take control of renourishing their child) will generalize to ARFID. The potential role of medication is also unknown. Although in clinical practice an appetite stimulant called cyproheptadine (CY) is sometimes used, a recent no-randomized case record review from a pediatric feeding clinic found that patients who took CY gained significant weight over a 6.5-month period, but remained in the underweight range at the end of the study and did not surpass weight gain in an unmedicated control group (46).

ARFID with avoidance based on the sensory characteristics of food: Individuals with heightened sensitivity to the taste or texture of novel foods, like Shoshannah, may present for treatment with a very limited diet and a desire to increase food variety. Motivation for increased food variety can range from counteracting the effects of poor nutrition, to enhancing self-esteem, to increasing opportunities to participate in food-related social activities (45). Techniques for increasing food variety include operant conditioning (a reward-based intervention style) and

systematic desensitization (modeling and hierarchical exposures) (47). A recent randomized controlled trial comparing operant conditioning to systematic desensitization for 2 to 6 year olds with selective eating found that, although both groups successfully added 7.9 and 4.7 new foods, respectively, compared to baseline, the two therapies did not differ significantly in terms of efficacy (48). Additionally, a recent case report described an adaptation of FBT in which parents supported their 11-year-old child in increasing the variety of foods consumed through family-oriented food exposure techniques (49).

ARFID with concern about the aversive consequences of eating: Individuals like Sarah who have had a traumatic experience with eating (e.g., choking or vomiting) may present to treatment having omitted foods that are similar to those that led to the aversive experience, or declining to eat altogether. Case reports of treatment for similar presentations have conceptualized this type of avoidance as a phobia and consequently utilized exposure techniques to reintroduce avoided foods (50,51). For example, one case report described the treatment of a 4-year-old boy who limited his intake to oatmeal, soft baby food, water, and protein drinks following a choking incident on partially solid food. He was able to successfully reincorporate solid foods (such as crackers and meats) via graduated exposure to increasingly feared categories of food using both office and in-home visits in order to generalize desired eating behavior across contexts (i.e., home, school, etc.) (52).

CONCLUSION

Although lesser known than other eating disorders, pica, RD, and ARFID can have serious physical and psychosocial consequences that impair both physical health and quality of life for many individuals. At present, there are no tested treatment manuals for any of these disorders, but each is an area of active research inquiry. Meanwhile, a comprehensive assessment is critical, and techniques already familiar to clinicians to treat classical eating disorders, anxiety disorders, low weight, and GI disorders may have heuristic value.

5.8 SUBSTANCE USE DISORDERS

CHAPTER 5.8 ■ SUBSTANCE USE DISORDERS

CHRISTIAN HOPFER, JESSE D. HINCKLEY, AND PAULA RIGGS

DEFINITION

Substance-related disorders encompass two major categories in *DSM-5*: substance use disorders (SUDs) and substance-induced disorders (SIDs) (1). Substances are divided into 10 classes, including alcohol; caffeine; cannabis; hallucinogens; inhalants; opioids; sedatives, hypnotics, or anxiolytics; stimulants; tobacco; and other or unknown. SUD is defined by cognitive, behavioral, and physiologic symptoms due to continued use of a substance despite significant substance use–related problems. Diagnostic criteria are divided into four central categories: impaired control over substance use (criteria 1 to 4), social impairment due to substance use (criteria 5 to 7), risky use of the substance (criteria 8 to 9), and pharmacologic criteria of tolerance and withdrawal (criteria 10 and 11, respectively). SUD can further be classified by severity based on the number of symptoms endorsed and by course specifiers. SID includes intoxication and withdrawal states, as well as other substance-induced mental disorders, related to each specific substance. Intoxication is defined as a constellation of reversible symptoms that develop during or shortly after recent ingestion of a substance and that are attributable to physiologic effects of the substance on the central nervous system (CNS). Intoxication only applies when symptoms of use result in problematic behavior. Withdrawal is defined as physiologic and cognitive symptoms due to reduction in or cessation of use of a substance that result in problematic behavioral change. In comparison to *DSM-IV* "abuse" and "dependence" are enfolded into the diagnostic criteria of SUD. Furthermore, the diagnosis of SID does not require nor preclude the diagnosis of SUD. The criteria for these diagnoses are described in Table 5.8.1.

TABLE 5.8.1

CRITERIA FOR SUBSTANCE USE DISORDER, INTOXICATION, AND WITHDRAWAL

Substance Use Disorder: Two or more within a 12-mo period

Impaired Control
1. Taken in larger amounts or over a longer period than intended
2. Persistent desire or unsuccessful effort to cut down or control use
3. Great deal of time spent to obtain, use, or recover from substance
4. Craving, or strong desire or urge to use

Social Impairment
5. Failure to fulfill major role obligations
6. Continued use despite social or interpersonal problems
7. Reduction in important social, occupational, or recreational activities

Risky Use
8. Recurrent use in physically hazardous situations
9. Continued use despite knowledge of physical or psychological problem

Pharmacologic Effect
10. Tolerance (need for increased amount or diminished effect)
11. Withdrawal (withdrawal syndrome or use to relieve/avoid withdrawal)

Intoxication
A. Recent ingestion
B. Problematic behavior or psychological changes
C. One or more sign or symptom attributable to the substance
D. Not attributable to another medical condition, mental disorder, or substance

Withdrawal
A. Cessation or reduction in heavy, prolonged use
B. Two or more signs or symptoms attributable to cessation or reduction in use
C. Clinically significant distress or impairment in important areas of functioning
D. Not attributable to another medical condition, mental disorder, or substance

HISTORY

Use and abuse of substances have been documented throughout history and date back to ancient times. The active ingredients in substances of abuse were initially identified and extracted during the 19th century, leading to an increase in the purity of substances available for consumption as more concentrated formulations were made. Initially, when substances such as opiates or cocaine were first identified, they were either freely available or prescribed widely by physicians and made available through many tonics. The liability of certain substances to result in "addiction" was recognized in the late 19th and early 20th centuries, when laws regulating substances of abuse were introduced. The 1914 Harrison Narcotic Act, which forbade the sale of cocaine or opiates except by licensed physicians or pharmacists, was one of the first laws introduced to regulate substances seen as having a liability for abuse. Also, the widespread perception that alcohol created societal problems led to the Prohibition Amendment of 1919 to the American Constitution, which made alcohol an illegal substance. This amendment, however, was overturned in 1933.

With the creation of the U.S. Federal Bureau of Narcotics (now the Drug Enforcement Administration) in 1930, the federal government took a more active role in regulating drugs and also defining which drugs could be legally purchased, could be available only by prescription, or would be completely banned. Throughout the latter half of the 20th century, major societal changes occurred in the acceptance and use of various substances—including marijuana, tobacco, cocaine, amphetamines, and "designer" drugs such as Ecstasy.

Along with changes in societal views and consumption of various substances came an increased scientific understanding of the mechanisms of actions of most addictive compounds, including the realization that these were binding to specific

brain receptor sites. Animal models of addiction established the neurobiologic basis for understanding addiction as a psychiatric illness (2).

EPIDEMIOLOGY

Annual surveys of US adolescents' drug use are conducted by the Monitoring the Future Survey (MTF) (3). Overall, American adolescents over the past decade have been using fewer substances, although there are some exceptions. Alcohol continues to be the most widely used substance among adolescents, with up to two-thirds of students having consumed "more than a few sips" of alcohol by the end of high school. Overall alcohol consumption has declined since the 1980s and is currently at the lowest level since the 1970s. However, lifetime prevalence of having been drunk in 2014 remains 11% among 8th grade and 50% among 12th grade students. Tobacco use has also continued to decline over the past decade and is currently at the lowest level since the 1970s. Thirty-day prevalence of cigarette smoking peaked in 1996–1997, and has fallen by 81%, 77%, and 63% since among 8th, 10th, and 12th grade students, respectively. In 2014, the estimated lifetime prevalence of cigarette use was 14% in 8th grade, 23% in 10th grade, and 34% in 12th grade. Increases in taxes on tobacco products may help explain the further decline in prevalence as perceived risk has remained level over the past decade.

The annual prevalence of using any illicit drug continued to decrease slightly, with the largest decrease among 10th and 12th grade students. Much of this decrease is likely due to a decrease in the annual prevalence of marijuana use over the past decade, though perceived risk of regular marijuana use is also declining. Marijuana remains the most widely used illicit drug among adolescents. While experimentation with alcohol and tobacco declined somewhat, marijuana experimentation increased from 35% in 1991 to a peak of 50% in 1997, and then drifted down again to approximately 45% in 2004. Over the past decade marijuana use prevalence again increased, peaking in 2010 to 2012. Overall roughly a third of twelfth graders reported lifetime experimentation with an illicit substance besides marijuana.

Opioid use is arguably the greatest adolescent and young adult substance use epidemic of the past decade. Illicit use of prescription opioids among 12th grade students nearly tripled from an annual prevalence of 3.3% in 1992 to a peak of 9.4% in 2004, declining to 5.4% in 2015. The annual prevalence of heroin use fell sharply in the latter half of the 1970s and remained steady through 1994. Heroin use again increased in the 1990s, along with increased use of most drugs, peaking in 2000 among 12th grade students at 1.5%. Prevalence again declined over 2005–2010, with slowing rates of decline in 2011, and have remained level since 2013 at 0.6% among 12th graders. Injection heroin use has also remained relatively stable among adolescents (3). Although the MTF study has found some decline in opiate use from peak levels in high school surveys, a number of other studies demonstrate the depth

of the adolescent opiate epidemic. Thus, in 2014 an estimated 467,000 adolescents were using opiates for pain relief, with approximately a third of these having an opiate use disorder. Another estimated 28,000 adolescents used heroin in the past year, and an estimated 18,000 adolescents had a heroin use disorder in 2014 (4).

TABLE 5.8.2

PRIMARY ADMITTING SUBSTANCE OF ABUSE (% OF TOTAL ADMISSIONS), BY AGE, FROM THE TREATMENT EPISODE DATA SET

Substance	Age 12–14 (%)	Age 15–17 (%)	Age 18–19 (%)	Age 20–24 (%)
Other/none	5.9	2.7	2.5	1.9
Alcohol only	6.9	4.3	9.0	11.1
Alcohol + secondary drug	6.4	8.3	11.7	12.3

(From TEDS. *Treatment Episode Data Set: 2003 Highlights. National Admissions to Substance Abuse Treatment Services, DASIS Series: S-27*. Rockville, MD; Services DoHaH (ed); 2005. DHHS Publication No. SMA 05–4043, with permission.)

The most commonly abused substances resulting referral of adolescents to publicly funded substance abuse treatment programs in the United States, by age group, are shown in Table 5.8.2 (5). For the youngest age group (12 to 14), marijuana constitutes the most frequently cited primary admitting substance of abuse. For the older (18 to 20) age group, marijuana and alcohol continue to represent a large portion of treatment admissions, but other illicit substances such as cocaine, methamphetamine, and heroin are more commonly cited as reasons for admission compared with younger adolescents.

While adolescents only represent 6% of the total patient population that accesses substance abuse treatment, 64.6% of all patients report first use of primary substance by 18 years old (5). The vast majority of patients entering treatment for alcohol, alcohol with a secondary drug, or marijuana use endorsed first use in adolescence (78.2%, 87.6%, and 92.1%, respectively). Over half of patients whose primary drug

is methamphetamines/amphetamines, hallucinogens, PCP, or inhalants also began use as teenagers, as well as 35.9% of heroin users and 35% users of other opiates. Although initiation and progression to SUD is common during adolescence, only an estimated 10% to 15% of adolescents who could benefit from substance treatment receive it. These findings strongly suggest the importance of improving drug and alcohol screening and developing earlier interventions for substance-involved adolescents and underscores the critical need to increase access and availability of substance treatment for youth and families.

General population surveys of adolescent SUDs indicate clear marked age trends. The prevalence of substance use and SUDs increases almost linearly from early to late adolescence (6). Approximately one in four older adolescents meets criteria for DSM-IV abuse for at least one substance, and one in five meets criteria for DSM-IV dependence (7). Nearly one in three adolescents reports daily smoking and 8.6% meet criteria for tobacco dependence by age 18. Although alcohol is the most commonly abused substance (10%), a slightly larger proportion of adolescents meet criteria for dependence on marijuana (4.3%) than alcohol (3.5%) (6). Additionally, there are gender differences, as males report more substance use than females, and more frequently meet criteria for dependence on alcohol and marijuana in late adolescence, while females are more often nicotine dependent (6). In clinical populations, rates of comorbidity are even higher. Approximately 60% of adolescents in juvenile justice settings and 40% in mental health treatment settings have co-occurring SUD (8) and as many as three-quarters of adolescents with SUD have other nonsubstance psychiatric disorders. The most frequent of these are externalizing disorders, but internalizing disorders are also more prevalent than in the general population. The Methods for the Epidemiology of Child and Adolescent Mental Disorders (MECA) study found past 6-month prevalence for comorbid psychiatric disorders with an adolescent SUD sample to be 76% for any comorbid disorder, 68% for any disruptive behavior disorder, 32% for any mood disorder, and 20% for any anxiety disorder (9).

ETIOLOGY

SUDs can only develop if substances are available for experimentation to occur. However, despite widespread availability of many substances, only a portion of youth experiment, and only a smaller percentage of those who do experiment go on to become regular users or to develop SUDs. Thus, the etiology of SUDs lies in those factors that predispose an individual to experiment with substances, and among experimenters, factors that predict progression to SUD. Although a comprehensive review of these substance-related risk factors is beyond the scope of this chapter, major theories about the etiology of adolescent SUDs are discussed below.

Genetic and Environmental Influences

Twin and adoption studies have demonstrated that considerable shared environmental influences exist for the initiation of substance use, with genetic influences becoming more apparent when environments allow for their expression (10). Thus, for example, Koopmans et al. (11) demonstrated that there were no genetic influences on the liability to initiate alcohol use when adolescents were raised in a religious household, but that 40% of the variation in initiation could be explained by genetic factors when adolescents were raised in a nonreligious household. Genetic influences on the development of adolescent SUDs may act through a direct effect on psychophysiological reactions or subjective effects (12) to substances or their metabolism, or indirectly through genetic effects on personality traits such as behavioral disinhibition, which leads to substance experimentation (13). Thus, genetic factors influence individual risk, but do not account for population-wide shifts in patterns of substance use.

Externalizing Disorders

Externalizing disorders have been shown to be major risk factors predicting the initiation of substance use and the development of abuse and dependence (14–17). Many of the risk factors associated with the development of externalizing disorders similarly predispose to the development of SUDs. Conduct disorder has consistently been shown to be a predictor of substance use initiation (18) and progression toward SUDs (19). Attention-deficit hyperactivity disorder (ADHD) appears to increase risk for developing SUDs somewhat, although there is controversy about the magnitude of the effect of ADHD due to its comorbidity with CD (20). Externalizing disorders and SUDs can also be thought of as influenced by one or more common antecedent risk factors (21).

Stage Theory and the "Gateway" Theory

Stage theory posits that there is a temporal ordering of substance experimentation in which lower-order substances, which are more commonly used, precede the use of higher-order substances. Thus, typically a licit substance, such as alcohol or cigarettes, is used first in a sequence, followed by marijuana, which is usually the first illicit substance before progressing on to use of other illicit substances (22). Related to stage theory is the gateway hypothesis as it relates to marijuana. This posits that the use of marijuana facilitates the entry into other illicit substance use.

A review of the available literature about the effect of marijuana use on other drug use concluded that there is a relationship between marijuana use and progression to other drugs. This effect can be explained by: (1) the selective recruitment to heavy

cannabis use of persons with pre-existing traits that predispose to the use of a variety of different drugs (i.e., that marijuana use is a marker for a tendency to use multiple drugs); (2) the affiliation of cannabis users with drug-using peers in settings that provide more opportunities to use other illicit drugs at an earlier age; and (3) that marijuana use results in socialization into an illicit drug subculture which creates favorable attitudes toward the use of other illicit drugs (23). Whether these relationships derived from past studies generalize to an environment where marijuana is legal for adult use is unclear however (24).

Early Onset of Use

Early onset of substance use has been shown to be a strong predictor for the development of SUDs over the lifetime (25). Whether this is due to early use being a marker for other risk factors that predict substance involvement or whether it has a causal effect is unknown. Animal work has suggested that the adolescent brain may be particularly vulnerable to the effects of drug sensitization, providing a possible neurobiologic explanation for the increased incidence of SUDs among those who begin drug use early (26).

Family and Peer Effects

SUDs tend to aggregate in families. This may be in part due to some common genetic influences within families; however, there is substantial evidence of environmental mediation. Parental drug use, as well as drug use by older siblings, is a significant risk factor for the development of adolescent substance use. However, the mechanism of transmission is complex, with individual personality dimensions mediating the effect of sibling and parent influences (27,28). Association with delinquent peers has been one of the hallmarks of the development of adolescent SUDs. However, while the common notion has been that peers create “peer pressure” to consume substances, most studies support the notion that there exists a complex process by which individuals select peer groups, and then in turn influence these, as well as are influenced by them (29).

Biologic Mechanisms in the Etiology of Substance Use Disorders

A large body of animal work has shown that repeated exposure to substances leads to neural adaptations altering the hedonic “tone” of individuals. This tone is reset by substance use so that it is lower over time, resulting in dysphoria and craving when not using, and driving the substance dependence cycle (30). This animal work has been key in demonstrating that all substances of abuse, although acting at different

receptors, create a common downstream pathway resulting in neural adaptations that perpetuate the addictive cycle.

Substance-Specific Risks

Although all substances of abuse share common neurologic pathways that are involved in the development of SUDs, there are differences between substances in terms of their addictive potential. The time course toward the development of dependence varies by individual, by substance, and by route of administration. Some substances, such as cocaine, are characterized by a rapid onset of the development of dependence, as for example, 6% of cocaine users develop dependence within one year of experimenting with cocaine (31). In a longitudinal study, Wagner and Anthony (32), for example, demonstrated that whereas some 15% to 16% of cocaine users had developed cocaine dependence within 10 years of first use, the corresponding values were about 8% for marijuana users, and 12% to 13% for alcohol users. There is growing evidence that adolescents may be more vulnerable to addiction compared to adults (26,33). For example, 1/6 adolescents who experiment with marijuana progress to dependence compared to about 1/11 adults (34).

DIAGNOSIS AND CLINICAL FEATURES

The diagnosis of SUD is made primarily through the clinical interview with the adolescent, as well as through obtaining collateral information from parents and teachers. Adolescents are likely to be in a "precontemplative" stage of change and may thus minimize the extent of their substance involvement (35). Establishing rapport with the adolescent is critical in order to increase the chance of self-disclosure of drug use. Early strong therapeutic alliance is facilitated by use of motivational interviewing (MI) style which is characterized by a nonjudgmental, collaborative approach (36).

Of primary clinical concern is the extent or severity of substance involvement, the specific substances that the patient is abusing or dependent on, and the length of time that the pattern has persisted. When an MI approach is taken and the limits of confidentiality are carefully explained to adolescents and parent/guardians, clinicians are much more likely to get an honest history of substance severity along with other behavioral problems.

When conducting an initial assessment with an adolescent for SUDs, the parents or caretakers should ideally be present during the initial interview, including discussion of the parameters and limits of confidentiality, and to obtain relevant developmental and family history. The interview with the parents or caretakers can also be used to obtain a history of the presenting complaint, early development history, and assess family dynamics. However, it is recommended that the substance use history be

obtained in a private interview with the adolescent because adolescents' self-reports of drug use have been shown to be more reliable when confidentiality is assured (37). The interviewing technique should be empathic, nonjudgmental, and supportive, using a MI approach to foster development of a strong therapeutic alliance (see http://www.motivationalinterview.org) (36). In general, the substance use history should be obtained with a similar style and sensitivity to obtaining medical/clinical information for any other disorder or evaluation of a medical review of systems. For substances that the adolescent reports using more than five times in his/her lifetime, clinicians should inquire about age of first use or experimentation, age of progression to regular use; peak use, current use (past month); and last use.

Following that, DSM-5 diagnostic criteria for SUD should be assessed to establish which SUDs should be targeted in treatment. Calendar-based timeline follow-back procedures (38) are often used at baseline/intake to better understand the current pattern and severity of substance use prior to treatment initiation. Other important information includes triggers for craving and use; context of use (e.g., with particular peers, or at or before school); perceived motivation for using; positive and negative consequences of use; and current motivation and goals for treatment (39).

Adolescents with SUD commonly meet diagnostic criteria for other psychiatric disorders. Thus, is quite important to obtain a longitudinal development history that enables the clinician to evaluate the temporal relationship between the onset and progression of psychiatric symptoms and the onset and progression of substance use. Use of a lifetime timeline to anchor this information is useful in consideration of differential diagnosis.

SPECIFIC LABORATORY TESTING OF SUBSTANCES—UPDATED

Detection of substances is a key component of SUD diagnosis and treatment. While the technologies to detect specific substances are changing, urinalysis remains the most commonly used method (for the detection of substances). Most commercial laboratories offer standard "panels" that may include the "NIDA 5." These are commonly abused substances that are detected by urinalysis. The NIDA 5 includes marijuana, cocaine, methamphetamine, heroin, and PCP, which were considered the most important substances to detect following passage of the Drug-Free Workplace Act of 1988. Table 5.8.3 shows the detection time of commonly tested substances by urinalysis.

There are a number of substances where urinalysis is ineffective or inefficient: Detection of alcohol use by urinalysis is limited by the quick elimination time of alcohol; similarly, detection of inhalants by urinalysis is ineffective. Detection of alcohol is usually done via breathalyzer. If inhalant abuse is suspected, a commercial product is a Toxtrap that will detect the presence of residual volatile organic

compounds. If there is a clinical suspicion of the abuse of hallucinogens, 3,4-methylenedioxymethamphetamine (MDMA), or GHB, usually specific laboratory tests for these must be ordered. Though commonplace, urinalysis of drugs of abuse is further limited in an evolving drug market of synthetic and designer drugs. Many synthetic cannabinoids, opioids, and amphetamines that are now widespread are not detectable by routine analysis (40). Many commonly used medications may result in false-positive detection of amphetamines, including pseudoephedrine, ephedrine, phenylephrine, and beta blockers propranolol and atenolol. Furthermore, doxylamine and dextromethorphan may result in false-positive detection of PCP. Ingestion of poppy seeds or hemp-containing food products may cause false-positive results for opioids and cannabinoids, respectively. Urinalysis may also be subverted by consuming free water (41,42); ingestion of "masking agents," though the concept is controversial (43); and adding adulterants to urine, including common household products ammonia, bleach, hydrogen peroxide, iodine, liquid soap, papain, and vinegar (43–46).

TABLE 5.8.3

URINE SUBSTANCE DETECTION PERIODS (TYPICAL)

Substance	Urine Detection Time
Alcohol	After absorption, decreases by –0.02 g%/hr
Amphetamine	24–72 hrs
Barbiturates	1–2 days
Benzodiazepines	3 days for therapeutic dose
Cannabis (single use)	1–3 days
Cannabis (moderate use)	3–5 days
Cannabis (heavy use)	10 days
Cocaine	24–96 hrs
Codeine/morphine	24–72 hrs
Heroin	24–72 hrs
Methamphetamine	24–72 hrs
PCP	14–30 days
LSD	1.5–5 days

Though urinalyses using immunoassays are considered specific and sensitive, urinalysis for drugs of abuse is less reproducible and may be unreliable when performed using on-site or point-of-care assays (47–49). Furthermore, proper training of personnel performing screening tests may significantly impact outcomes (50). If laboratory testing is going to be used in a legal proceeding, the laboratory must meet certain standards defined in federal law as the Clinical Laboratory Improvement Amendments (CLIA). In addition, for youth with chronic A-9 tetrahydrocannabinol (THC) use, a quantitative test is available that will show a decline in use over time, and thus can distinguish current from past use (51).

SUBSTANCE-SPECIFIC CLINICAL FEATURES

While all SUDs have common features that are characterized by the criteria for abuse and dependence, there are substance-specific issues of clinical relevance.

Alcohol

Alcohol is one of the first substances that adolescents usually experiment with, and alcohol use disorders constitute a major proportion of adolescent SUDs (4). The acute effects of alcohol intoxication include sedation, loss of balance, restlessness, slurred speech, decreased heart rate, and lowered blood pressure. Tolerance to alcohol develops with repeated ingestion, and withdrawal symptoms, although rare in adolescents, can be observed. These may include increased heart rate, elevated blood pressure, elevated temperature, vomiting and diarrhea, sweating, and possibly confusion, seizures, delirium, or psychosis. Withdrawal from alcohol can be medically life threatening and may need to be managed in a medically supervised setting. Detection of alcohol use is usually accomplished via breathalyzer, as its detection time in a urinalysis is limited.

Tobacco

The addictive ingredient in tobacco is nicotine, which has been shown to produce dependence in a substantial proportion of users (52). The primary concern with tobacco dependence is the long-term medical sequelae of use, as well as evidence that consumption of tobacco may facilitate the use of other substances. Nicotine is rapidly absorbed through either smoking or chewing and results in CNS stimulation, followed by withdrawal symptoms. It binds to the nicotinic acetylcholine receptors. Blood and brain levels of nicotine increase with each puff of a cigarette, and nicotine accumulates throughout the day. The half-life of nicotine is usually about 2 hours. Withdrawal symptoms from nicotine typically include craving, irritability, difficulty concentrating, and possibly anxiety and depressed mood.

Marijuana

Marijuana use disorders accounts for the largest proportion of adolescent SUDs (4) and recent changes in state-by-state marijuana policies have multiple implications for adolescents (24). There is mixed evidence regarding the effect of medical marijuana laws on adolescent marijuana use, with some evidence that states that enacted laws already had more liberal attitudes toward marijuana consumption (53–55). However, commercialization allowing operation of dispensaries is associated with increased use and decreased perceived risk among adolescents and young adults (56). Laws

legalizing and regulating the marijuana industry also do not provide guidelines for potency or set limits on maximum potency of marijuana products (57). Thus, commercialized marijuana products have higher potency based on strain and can be further concentrated in edibles or other products than marijuana purchased on the black market. Medical marijuana is also diverted to adolescents (58,59). Treatment-seeking teens who reported diversion of marijuana were also more likely to report easy availability, no friend disapproval of regular marijuana use, increased use, and more substance use problems (58).

There is a paucity of data on the impact of state laws legalizing recreational marijuana in the United States. Two approaches to decriminalize marijuana possession have been implemented regionally in Europe and elsewhere: depenalization and legalization (60). Legalization of recreational marijuana provides a path to commercialize marijuana sales, which subsequently is associated with decreased risk perception and increased access and use similar to medical marijuana commercialization. Among US high school seniors, 10% of non–marijuana-using students and 18% of lifetime marijuana-using students report intent to initiate or increase use of marijuana, respectively, if recreational marijuana was legalized. Thus, policies decriminalizing recreational marijuana use in the United States are likely to have varying effect determined by approach, limitations, and implementation.

As marijuana policies have evolved over the last decade, much has been learned about marijuana's effect on the brain and development. The active ingredient in marijuana is A-9 tetrahydrocannabinol (THC). THC binds to the cannabinoid receptor (CNR1), which is broadly distributed throughout the CNS. The endogenous cannabinoid system is an important neurotransmitter system involved in memory formation, appetite regulation, and coordinated movement. Brain development continues through adolescents, with increases in white matter volume and development of functional connectivity underlying tasks such as executive function (61,62). Analysis of the Dunedin Study (prospective cohort of 1,037 individuals followed from birth to 38 years old) showed that persistent marijuana use in adolescence was associated with a decline in intelligence quotient (IQ) among multiple domains (63). IQ did not fully recover after cessation, which is consistent with previous research demonstrating persistent neuropsychological deficits in executive function and psychomotor speed tests during prolonged periods of abstinence (64–66). Longitudinal functional MRI (fMRI) analysis of treatment-seeking adolescents and healthy controls demonstrated a dose-related decrease in functional connectivity of cortices essential for executive functioning over time (67). High amounts of marijuana use was also associated with lower IQ and slower cognitive function.

Marijuana has a range of effects on the user, consistent with the widespread distribution of the CNR1 receptor. It may have sedative, analgesic, hallucinogenic,

appetite-enhancing, and anxiolytic properties for the user. It usually results in a relatively short-lived intoxication state, often characterized as euphoria. THC intoxication impairs cognitive and psychomotor performance, although it is unclear currently if these effects persist after abstinence. There is also increasing evidence that marijuana use may be a causal factor in the development of other psychiatric disorders. In particular, evidence points to marijuana use increasing the risk for developing psychosis, as well as other psychiatric disorders (34). It remains unclear how higher-potency marijuana products will affect prevalence and severity of cannabis-induced psychiatric disorders. Cannabis withdrawal syndrome, which is now recognized in *DSM-5* consists of including irritability, anger, aggression, anxiety, sleep disturbance, restlessness, and depressed mood (1,68).

Opiates

Heroin use and abuse of prescription opiates has risen during the past two decades. Adolescents are commonly exposed to prescription opioids, with an estimated one in four high school seniors in the United States endorsing use of these drugs either medically or nonmedically between 2007 and 2009 (69). In a recent epidemiologic study, 12.9% of high school seniors report nonmedical use of prescription opioids, of whom over half were given the drugs for free by friends or relatives (69). Another survey of 14- to 20-year-old patients at university-affiliated emergency departments found that 8.7% report nonprescription opioid use (70). Furthermore, ambulatory opioid prescriptions for adolescents and young adults nearly doubled between 1994 and 2007, including for noninjury encounters (71).

Regional studies from across the United States estimate 39% to 86% of young adults used nonmedical opioids prior to transitioning to heroin (72–77). As shown in analysis of 2011–2013 national data, frequent nonmedical opioid use is the most significant risk factor for heroin use (odds ratio 40, 95% CI 24.6–65.3) (78). However, the conversion rate to heroin has remained low overall. The price of heroin has decreased ($465 in 2012 per gram compared to $2,690 per gram in 1982) and more readily available (78–80). The increasing purity of heroin has made it possible to smoke or snort it, and this has led to an increase in its use over the past decade among adolescents. Heroin dependence in adolescents is typically associated with a rapid psychosocial decline, school failure, criminal behaviors, and family problems (81). The intense pleasurable effects of heroin are largely responsible for the addictive potential of heroin and tolerance may develop rapidly.

Unintentional death due to opioid overdose has been on the rise over the past 30 years, with the most dramatic increases in over the past decade (82). This rise in opioid deaths contributed significantly to unintentional overdose becoming the second most common cause of accidental death in the United States by 2007. Designer opioid drugs are up to 1,000 times more potent than heroin, with frequent

changes in formulation (83,84). Furthermore, heroin is often adulterated with various agents, including prescription drugs, resulting in compounds that differ in final concentration by up to 20-fold (85). Thus, opioid use is more likely to result in unintentional overdose than abuse of other substances.

Opioid ingestion affects multiple organ systems and can result in a life-threatening toxidrome. Intoxication may produce analgesia, euphoria, or dysphoria. Physical symptoms often include miosis, flushing, nausea, emesis, and constipation. Co-ingestion of contaminants such as cocaine or anticholinergics may cause mydriasis or normal pupils confusing the clinical picture. Opioids cause both CNS and respiratory depression, ranging from altered mental status and bradypnea or hypopnea to coma, apnea, and noncardiogenic pulmonary edema. Patients may also have bradycardia, hypotension, cardiac arrhythmias, or seizures. Arrhythmias are caused by opioid effects on ion channels within the heart or contaminants mixed with opioids. Early stages of opioid withdrawal manifest as anxiety, insomnia, restlessness, diaphoresis, abdominal discomfort, and rhinorrhea. Symptoms of fevers, chills, emesis, diarrhea, muscle spasms, and tremors may persist for 3 days after last ingestion. Other clinical signs of withdrawal include tachycardia, hypertension, and tachypnea.

Cocaine

Physical effects of cocaine use include constricted blood vessels, dilated pupils, increased temperature, heart rate, and blood pressure. The duration of cocaine's euphoric effects, which include hyperstimulation, reduced fatigue, and mental clarity, depends on the route of administration. The faster the absorption, the more intense the high and the shorter the duration. The high from snorting may last 15 to 30 minutes, while that from smoking may last 5 to 10 minutes.

Amphetamines

Methamphetamine is known by a variety of street names including ice, speed, crystal, glass, and crank. It is an addictive stimulant that can be smoked, injected, or inhaled. Its use is associated with major health consequences, including memory loss, aggression, violence and psychotic behavior, and neuropsychological deficits (86). Similar to cocaine, dependence can develop quickly and be associated with rapid psychosocial decline. The physical effects of acute intoxication include increased wakefulness, increased physical activity, decreased appetite, increased respiration, hyperthermia, and euphoria. Convulsions and seizures may occur.

MDMA

Past year use of MDMA, or ecstasy, surged in the early 2000s to its highest

prevalence, subsiding by 2004. Over the past decade MDMA past year prevalence peaked again in 2010, subsequently declining to 0.9%, 2.3%, and 3.6% of 8th, 10th, and 12th grade students in 2014 (3). This represents all-time lows among adolescents less than 16 years old. MDMA is a synthetic drug with both psychedelic and stimulant effects. In the past, some therapists in the United States used the drug to facilitate psychotherapy. In 1988, however, MDMA became a Schedule I substance under the Controlled Substances Act. MDMA is a stimulant usually taken orally in pill form and whose psychedelic effects can last between 4 and 6 hours. The psychological effects of MDMA include confusion, depression, anxiety, sleeplessness, and paranoia. Physical effects may include muscle tension, involuntary teeth clenching, nausea, blurred vision, feeling faint, tremors, rapid eye movement, and sweating or chills. In rare cases, severe hyperthermia may develop. The epidemiologic evidence suggests that most users do not develop dependence upon MDMA and that its use spontaneously remits in the early 20s. However, a minority of users, primarily those who meet dependence symptoms, will continue to use MDMA (87).

GHB

Approximately 2% of US high school seniors reported using gamma hydroxy butyrate (GHB) within the past year (8). GHB is known by such street names such as "grievous bodily harm," "G," or "liquid ecstasy." It is a CNS depressant originally sold in health food stores as a muscle growth agent. The effects of GHB have been described as being similar to those of alcohol, except that periods of unconsciousness appear to be more frequent and unpredictable. Effects usually last about 4 hours. Some users report developing dependence upon GHB and experience rebound symptoms, with features similar to benzodiazepine withdrawal.

Inhalants

Approximately 5% of US high school students reports having tried inhalants at least once in the past year (3); however, rates of inhalant abuse or dependence are much lower, as only 0.1% of adolescents report abuse or dependence upon inhalants (88). Inhalants are volatile organic compounds that include many gases and fumes that are deliberately taken in order to achieve intoxication. Their abuse is more common among young adolescents, since these are some of the first substances available to them. Inhalants may be taken by directly spraying them into the mouth, "huffed"—meaning that the substance is held in a cloth and several breaths are taken, or "bagged"—meaning that the vapors are inhaled from a bag. The acute effects of inhalant intoxication resemble alcohol intoxication in that the youth often experiences acute euphoria and disorientation, which may be followed by a period of drowsiness,

as inhalants are CNS depressants. Because inhalants encompass a wide range of possible compounds, it is not possible to cover all aspects of their presentation. However, inhalant use may quickly result in neurologic sequelae and persistent use has been associated with white matter changes and loss of cognitive performance. Due to the neurotoxicity of inhalants, any use must be taken seriously.

Steroids

Approximately 0.6% to 2.0% of male US high school students report having used anabolic steroids within the past year, which is down by approximately half among younger adolescents over the past decade (3). Steroids are used generally not in order to achieve an immediate pleasurable effect, but in order to increase muscle mass, and thereby body image. Thus, the abuse of steroids differs from abuse of other substances, which are usually taken because of their immediate, rewarding effects. Steroids are typically taken in order to achieve a long-term goal: improved body image or physical performance. Anabolic steroids are usually taken in "cycles" and typically combined with weight-lifting regimens. There are numerous medical consequences of administering exogenous steroids, including premature growth stoppage and either shrinking testicles for men or the development of male sexual characteristics for women. In addition, mood swings or psychotic episodes may result from steroid abuse. Details of the medical and psychiatric sequelae are described by Brown (89).

COURSE AND PROGNOSIS

The course and prognosis of SUDs is varied. Earlier onset, more severe substance use, and comorbid conditions predict a more severe course and outcome. In general, substance disorder implies a chronic, relapsing condition.

Treatment

Treatment for adolescent SUDs involves recognizing that these are chronic relapsing conditions. Patients may need multiple episodes of treatment over time. Treatment typically involves initial attempts to create abstinence or markedly reduced drug use, a period of addressing the biopsychosocial aspects of SUDs, and a maintenance or "relapse prevention" phase. Adolescents usually do not self-refer for treatment, but are often pressured into treatment by family, school, or court. They often present as defiant, or minimizing of their drug use. The primary initial goals of treatment are to engage the adolescent and the family in processes that interrupt drug-seeking and drug-using behaviors and to replace these with prosocial behaviors. A variety of evidence-based approaches have been shown to be successful. Typically, effective

treatments are multimodal and address individual, family, peer, and other social environment domains simultaneously. Pharmacotherapy may be an important component for certain SUDs, as well as comorbid conditions.

Specific Therapeutic Approaches

Motivational Interviewing

Motivational enhancement techniques have been demonstrated to promote treatment engagement and can be used to establish a strong treatment alliance and to elicit patient-generated treatment goals (90). This approach increases the patient's motivation to change by increasing the frequency and strength of "change talk," which in turn is positively correlated with making behavioral changes. Adolescents are generally resistant to more directive, confrontational approaches and are often ambivalent and relatively unmotivated for treatment, making motivational approaches critical. MI principles can be effectively used in conjunction with cognitive-behavioral or family-based treatment (91,92).

Cognitive-Behavioral Therapy

Cognitive-behavioral therapy (CBT), based on learning theory, also has been shown to be effective in treating adolescent SUDs (93). Treatment manuals have been developed for courses of weekly CBT treatment ranging from 5 to 16 weeks. Both group and individual format CBT have been shown to reduce adolescent SA and improve related behavior problems (94). However, individual CBT has more consistently been associated with sustained or even emerging treatment effect size (92). CBT typically relies on a "functional analysis" that identifies reinforcers of substance use as well as competing behaviors, skills deficits, and specific cognitive distortions associated with substance use. An important feature of CBT is its emphasis on skills training used to enhance coping strategies to deal effectively with drug cravings, regulate negative mood states, avoid high-risk situations; and strengthen problem solving and communication skills (95).

Family and Multisystemic Therapies

A range of family-based therapies have been shown to be successful in treating adolescent SUDs. Family and multisystemic therapies all treat adolescents within the context of their environment, and try to modify multiple environmental factors contributing to SUDs (96). These approaches have been widely studied and shown to be effective for adolescent SUDs. Multisystemic therapy is an approach that addresses social and family influences of drug use and associated antisocial behaviors. Therapists make frequent home visits and are available on a full-time

basis to families. Henggeler et al. (97) demonstrated that over 98% of youth receiving MST remained in treatment, compared to very few youth in a control group accessing treatment. Other approaches include brief strategic family therapy, which is a less intensive approach and can be delivered through weekly office visits. Other family therapies include multidimensional family therapy (98), which has also reported positive outcomes in controlled, randomized trials.

Community Reinforcement and Behavioral Approaches

Community reinforcement therapy is a skills-based approach to treatment that focuses largely on changing environmental factors in the community in order that nonusing behaviors be rewarded. A manual has been developed for the treatment of adolescent cannabis use (the most common presentation for adolescents with SUDs), and is available from the Substance Abuse and Mental Health Services Administration. This approach, and similar ones that focus on altering environmental rewards for drug use and non–drug-using behaviors, has been shown to be superior to a supportive model (99). The primary goal of these approaches is to promote abstinence by altering the conditions that promote substance use. Typically, therapists conduct a functional analysis of substance use that identifies antecedents to drug use, actual behaviors, and positive and negative consequences of substance use. Therapists aim to promote positive social activities that are not compatible with drug use and improve relationships with family members. The primary goal with parents is to motivate them to participate in the community reinforcement process and to teach the family members skills to promote abstinence and discourage drug use. Furthermore, other systems such as school or probation may be engaged in order to affect their behavior to promote adolescent abstinence. Waldron et al. (91) demonstrated that it was possible to engage 71% of treatment-resistant youth in treatment using a community-reinforcement family therapy model. Both parents and youth showed significant improvements in multiple domains of functioning and significant reduction in drug use for the youth who participated in treatment.

Contingency Management

Contingency management (CM) is based on well-established principles of behavioral reinforcement. The use of CM in the treatment of addiction has shifted away from negative reinforcement approaches (e.g., confrontation, punishment) and toward more positive reinforcement approaches. For example, abstinence is often reinforced by providing tangible rewards (vouchers or opportunities to draw for prizes) for urine drug screens. Numerous studies in adults and an increasing number of adolescent studies show higher rates of abstinence when CM is added to other psychosocial substance treatment interventions (100–102). For example, most adolescent psychosocial substance treatment interventions report that 10% to 30% achieve

abstinence during treatment compared to approximately 50% with the addition of CM/abstinence-based incentives (101,103). The addition of contingencies can help retain adolescents in treatment as well as improve outcomes (104,105).

Pharmacotherapies

For many SUDs, there are no effective pharmacotherapies. However, for the abuse of alcohol, nicotine, and opioids, there are effective pharmacotherapies. In addition, comorbid conditions may often be the target of pharmacotherapy. These are described in Tables 5.8.4 and 5.8.5.

Integrated Mental Health and Addiction Treatment Principles

Taken together, current research indicates that most adolescents with SUD have other nonsubstance psychiatric disorders and poorer substance treatment outcomes compared to noncomorbid youth with SUD. There is also considerable consensus among both researchers and clinicians that treatment for co-occurring disorders should be integrated or concurrent treatment. Despite practice parameters recommending integrated treatment (116), existing evidence-based substance treatment interventions and most adolescent substance treatment programs do not systematically assess or concurrently treat co-occurring substance and other psychiatric disorders. Progress toward integrated mental health and substance treatment has been impeded by the lack of dually trained clinicians, systemic and economic barriers, and limited research to guide integrated treatment approaches. However, in the context of national healthcare reform (e.g., Affordable Care Act, 2010; Mental Health and Addiction Parity Act, 2008) there are early signs of progress toward greater integration of mental health and addiction treatment and behavioral health integration within mainstream medical care. There has also been progress in research that informs the development of integrated treatment models, including a handful of controlled pharmacotherapy and behavioral treatment trials of adolescents with SUD and other psychiatric comorbidities. Taken together, results of these studies, summarized below, provide an important foundation from which research-based principles for integrated treatment can be derived.

TABLE 5.8.4

COMMON COMORBID DISORDERS PHARMACOTHERAPY FOR ADOLESCENTS WITH A SUBSTANCE USE DISORDER

Comorbid Disorder	Effective Treatment for Adolescents without SUD	Impact of Treatment on Adolescents with SUD
Attention-deficit hyperactivity disorder	• First line: pharmacotherapy (generally; psychostimulants) • Medication options with low abuse potential: pemoline, bupropion,	**One controlled trial of pemoline (Riggs et al., 2004 (106); *N* = 69) suggests:** • Efficacy for ADHD despite

(ADHD)	atomoxetine	nonabstinence • Good safety profile in 12-wk trial; potential for hepatotoxicity, relative contraindication for pemoline • No decrease (or increase) in drug use in the absence of specific behavioral intervention for SUD • Potential for hepatoxicity relative contraindication for pemoline given other current options • Clonidine relatively contraindicated
Bipolar disorder	• First line: pharmacotherapy • Mood stabilizers (lithium, valproic acid, carbamazepine)	**One randomized controlled trial of lithium in adolescents with SUD and comorbid bipolar (Geller et al., 1998 (107); *N* = 25) suggests:** • Efficacy and reasonable safety for bipolar disorder despite nonabstinence • Not adequate as an effective treatment for SUD in the absence of specific behavioral treatment for SUD
Depression	• First line: combined pharmacotherapy and psychotherapy • Pharmacotherapy: SSRIs (> support, fluoxetine) in adolescents without SUD • Psychotherapy: cognitive-behavioral therapy (CBT) and interpersonal psychotherapy, combined with medication for severe depression fluoxetine + CBT > efficacy than either alone (TADS study March/TADS team 2004, *JAMA*) (108)	**One randomized controlled trial of fluoxetine in adolescents with SUD and comorbid MDD + CBT for SUD (Riggs et al. (109); *N* = 126) suggests:** • Efficacy for depression despite nonabstinence (16-wk trial) • Good safety profile. • High rate of depression remission in both fluoxetine and placebo-treated subjects suggests that CBT also + impact on depression despite focus on drug abuse, not depression • Remission of depression, regardless of medication assignment, was a more important predictor of decreased drug use than fluoxetine vs. placebo • Remitters drug use decreased significantly; nonremitters had no change in drug use • Tricyclics relatively contraindicated in adolescents with SUD (e.g., arrhythmias; anticholinergic adverse effects)
Anxiety disorder (often comorbid with depressive disorders)	• First line: combined psychotherapy (CBT) and pharmacotherapy (> evidence, SSRIs)	**40% of adolescents in aforementioned controlled trial of fluoxetine for MDD in adolescents with SUD (Riggs et al., 109) suggests:** • Fluoxetine efficacy and safety in reducing symptoms of anxiety in depressed, substance-dependent

		adolescents with significant anxiety symptoms and/or anxiety disorders (GAD, SAD, PTSD) • No difference in depression and drug use outcomes comparing those with and without anxiety disorders

TABLE 5.8.5

PHARMACOTHERAPIES FOR ADOLESCENT SUBSTANCE USE DISORDER

Substance	Medication	Dose	Comments
Alcohol	Disulfiram	250 mg po qd or 500 mg po qod	FDA approved for alcohol dependence in adults Carroll et al. (110) showed that, in adults, it was also effective for cocaine dependence when alcohol involved
	Acamprosate	1–4 g per day given in a tid dosing schedule	FDA approved for alcohol dependence in adults. One study (Niederhofer and Steffan (111); *N* = 26) suggests similar efficacy in adolescents as for adults
	Naltrexone	50 mg po qd, also available in injection form	FDA approved for alcohol dependence in adults. Deas et al. (112) showed in open-label trial (*N* = 5) that it was safe and well tolerated
	Topiramate	25–300 mg po qd	Not FDA approved yet. Review by Johnson (113) indicates effectiveness for adults
Nicotine	Bupropion Nicotine patch	100–300 mg po qd Varies depending upon product	FDA approved for smoking cessation in adults
Opiates	Methadone	Varies	Adolescents under 18 must have two documented failures at drug-free detoxification. Needs to be prescribed at a certified clinic. See Hopfer et al. (114).
	Buprenorphine	8–32 mg	Marsch et al. (115) showed effectiveness for adolescent detoxification in randomized controlled trial. However, consider maintenance therapy.
	Naltrexone	50 mg po qd	Low compliance without monitoring. Injectable form has been approved and is available (Vivitrol).

Only a handful of controlled pharmacotherapy and behavioral intervention trials have been conducted in adolescents with co-occurring substance and nonsubstance psychiatric disorders. The strikingly similar results of three similarly designed studies are particularly informative and relevant to integrated treatment principles. In the first study, 126 adolescents (ages 13 to 17) meeting DSM-IV diagnostic criteria for major depressive disorder (MDD), lifetime conduct disorder (CD), and at least one nontobacco SUD were randomized to 20 mg daily dose of fluoxetine or matching placebo. Participants in both groups received weekly, individual MET/CBT as outpatient substance treatment throughout the 16-week medication trial. Fluoxetine

showed greater efficacy compared to placebo on reductions in Childhood Depression Rating Scale-Revised (CDRS-R) scores (primary outcome measure). Reductions in substance use were clinically and statistically significant in both groups but not different between groups (109).

Rates of depression remission (defined as final CDRS-R raw score ≤28) were unexpectedly high in both the fluoxetine (70%) and placebo (52%) treatment groups. This led investigators to speculate that CBT (targeting substance abuse), received by participants in both groups, may have contributed to depression treatment response despite its primary focus on substance abuse. Similar findings have been reported in adult studies including a meta-analysis of controlled antidepressant medication trials (mostly serotonin reuptake inhibitors/SSRIs) in adults with co-occurring depression and SUD. The authors concluded that mixed findings across studies were due to an unusually high "placebo response rate" especially in the studies in which participants concurrently received individual CBT as outpatient substance treatment (40,41).

Two similarly designed controlled trials of pharmacotherapy for ADHD in adolescents with SUD reported similar results. The first was a multi-site placebo-controlled trial of Osmotic-Release Methylphenidate (OROS-MPH) conducted in the NIDA Clinical Trials Network (CTN). In this study, 303 adolescents (ages 13 to 17) meeting DSM-IV diagnostic criteria for ADHD and SUD were randomized to OROS-MPH or matching placebo across 11 participating sites. Adolescent participants assigned to both groups received individual, manual-standardized MET/CBT as outpatient substance treatment throughout the 16-week medication trial. Results showed significant reductions in ADHD symptom severity and substance use in both groups but no difference between groups on either the primary ADHD (ADHD-RS) or primary substance (change in days of past 28-day substance use) outcome measures. Some secondary outcome measures suggested "added benefit" with OROS-MPH compared to placebo treatment. Specifically, participants treated with OROS-MPH reported greater improvement in their problem-solving and coping skills related to substance use and had more negative urine drug screens compared to participants in the placebo group (43).

A similarly designed randomized controlled trial of atomoxetine versus placebo in 70 adolescents (ages 13 to 18) with ADHD and SUD reported similar findings. Participants in both groups received individual MET/CBT as outpatient substance treatment throughout the 12-week medication trial. Both groups showed significant and comparable reductions in ADHD symptom severity (ADHD-RS) and substance use (days of past 28-day substance use) but no difference between groups on either primary outcome measure (44).

The higher than expected placebo response rates in both of these adolescent studies led authors to speculate about the potential contribution of CBT to ADHD symptom reduction. Similar findings have been reported in adult studies. For example, in a 12-week, 3-arm trial comparing methylphenidate (MPH), bupropion, or

placebo for ADHD in adults receiving concurrent CBT (outpatient SUD treatment), all groups showed significant reductions in ADHD symptoms but no difference between active medication and placebo groups (45).

Two other placebo-controlled trials of MPH for ADHD in cocaine-dependent adults also reported no greater improvement in ADHD with MPH treatment compared to placebo in the context of concurrent weekly CBT (outpatient substance treatment) (46,47). This is in contrast to two randomized placebo-controlled trials of pemoline (adolescent study) and atomoxetine (adult study) reporting moderately greater efficacy for active medication compared to placebo for ADHD in participants who did not receive concurrent CBT or other psychosocial substance treatment during these trials (48,49).

Implications for Integrated Mental Health/Substance Treatment

Taken together, results of these studies have important implications for clinical practice and provide a foundation for deriving research-based principles for integrating the treatment of SUD and other co-occurring psychiatric disorders:

1. Each of these studies utilized a standardized and comprehensive semi-structured diagnostic interview to determine substance and other psychiatric diagnoses at baseline.
2. Based on psychiatric diagnosis (e.g., MDD/CDRS-R; ADHD/ADHD-RS) psychometrically valid and clinically informative measures of psychiatric symptom severity were administered at baseline and repeated at least monthly throughout treatment to monitor changes in psychiatric symptom severity in response to treatment.
3. Changes in substance use was assessed at baseline and throughout treatment using standard TLFB procedures based on self-reports. Urine drug screens were also obtained at baseline and weekly during treatment as a biologic measure of substance use.
4. The medications used in the aforementioned trials (i.e., fluoxetine, OROS-MPH, atomoxetine) demonstrated relatively good safety profiles, despite nonabstinence in most participants, in the context of concurrent participation in substance treatment and regular safety monitoring. This suggests that these medications may be considered to treat co-occurring depression or ADHD if psychiatric symptoms are not significantly improving during the first month of substance treatment, even in patients who have not yet achieved abstinence.

Finally, the consistency of findings across adolescent and adult studies showing significant reductions in psychiatric symptom severity or high “placebo response rates” in the context of substance treatment with individual CBT warrants additional research and studies specifically designed to determine the separate and combined

contribution of CBT (targeting SUD) to treatment response for other (nonsubstance) co-occurring psychiatric disorders.

CONCLUSION

Adolescent substance use present in a myriad number of ways in clinical settings. Often the use of substances may complicate the assessment or treatment of another psychiatric conditions and the primary clinical task is to establish whether a use disorder exists. In other contexts, the substance use disorder is primary and potentially life threatening. Placement criteria developed by the American Society of Addiction Medicine are commonly used to determine level of care (117). While the mainstay of treatment consists of multimodal psychosocial treatments, pharmacotherapy has an important role in the management of co-occurring psychiatric disorders, nicotine and alcohol use disorders, as well as for opiate use disorders, where pharmacotherapy (either agonist or antagonist) is the standard of care.

5.9 SLEEP DISORDERS

CHAPTER 5.9 ■ SLEEP DISORDERS

ARGELINDA BARONI AND THOMAS F. ANDERS

INTRODUCTION

Sleep is crucial for emotional, cognitive, and physical well-being. Most psychiatric conditions are associated with sleep disorders (1); additionally, sleep disturbances are risk factors for the development of mood, anxiety, and substance use disorders and suicidal behaviors (1,2). Insufficient or disrupted sleep in children and adolescents is also associated with sport and motor vehicle accidents and metabolic disorders, including increased obesity and insulin resistance (2,3).

Sleep complaints are common among both typically developing children and children with psychiatric and developmental disorders (4). Moreover, population-wide studies have found a high prevalence of children getting inadequate sleep (5). Unfortunately, most medical and mental health professionals receive insufficient training in sleep medicine and parental knowledge on sleep is limited (4,6,7). For these reasons, sleep disorders are vastly underdiagnosed and undertreated, despite strong evidence for effective interventions (8). This chapter begins with a brief overview of normal sleep physiology, sleep assessment, and prevention across development and concludes with an overview of common pediatric sleep disorders. For simplicity, we will refer to children and adolescents as children throughout, except when referring specifically to adolescents.

TABLE 5.9.1

FEATURES OF NREM SLEEP AND REM SLEEP

NREM Sleep	REM Sleep
EEG: synchronized, slower frequencies and higher voltages than wakefulness and REM	EEG: desynchronized, mixed, low amplitude fast frequencies, similar to wakefulness
Reduced metabolic activity	Increased metabolic activity
Autonomic slowing	Autonomic activation
Maintained thermoregulation	Altered thermoregulation: poikilothermia
Episodic, involuntary movements	Skeletal muscle atonia
Slow rolling eye movements	Rapid eye movements
Few penile erections or little vaginal lubrication	Partial or full penile erections or significant vaginal lubrication
Limited mentation/dreaming	Dreaming
Defined as quiet sleep in infants	Defined as active sleep in infants
Sleepwalking and sleep terrors arise from NREM sleep	Nightmares arise from REM sleep

SLEEP PHYSIOLOGY

Behaviorally, sleep can be defined as perceptual disengagement from the environment that is easily reversed with intense stimulation and is accompanied by specific physiologic concomitants. These include variations in brain and cardiovascular activity, muscle tone, breathing pattern, and body temperature. Physiologic systems are routinely recorded via polysomnography (PSG) in the sleep laboratory or, increasingly, at home. Eye movement, muscle tone, and electroencephalographic (EEG) patterns are the primary parameters used to score the two major sleep states, non–rapid eye movement (NREM) and rapid eye movement (REM) sleep. These states alternate cyclically throughout the night. NREM sleep is further divided into N1, N2, N3 "stages" based on EEG characteristics. N1 is the lightest sleep stage, characterized by limited sensory disconnection, while N3, also called "deep sleep," is characterized by slow-wave activity, disengagement from the environment, and a high arousal threshold. See Table 5.9.1 for differences between REM and NREM sleep. Patterns of abnormal breathing, heart rate irregularity, and episodic behaviors, including limb movements, can be observed during PSG and are associated features useful in diagnosing specific sleep disorders. PSG can also be used to assess quantitatively the amount of excessive daytime sleepiness that patients with disorders of hypersomnolence experience, with the Multiple Sleep Latency Test (MSLT) protocol (9). The test is done in a sleep laboratory and uses PSG to measure the amount of sleep obtained during five 20-minute trials, from midmorning to early evening, usually after a nocturnal PSG. At each 20-minute period, the subject tries to fall asleep, and the latency to sleep onset for each attempted nap represents how sleepy the individual is. The test, standardized for use with adults and for adolescents, is a sensitive indicator of sleepiness and is significantly correlated with the performance decrement associated with sleepiness.

SLEEP–WAKE STATE ORGANIZATION ACROSS DEVELOPMENT

The characteristics of the electrophysiologic patterns and the proportions of sleep–wake states change markedly across development as a function of multiple processes, including myelination, cortical synaptic density, and circadian system maturation. Adult sleep organization is achieved by early adolescence. Neonates and infants have shorter sleep cycles (~50 minutes) compared to older children, adolescents, and adults (90 to 120 minutes) (10). Moreover, their sleep cycles are characterized by sleep-onset REM (active) sleep and higher proportion of REM sleep (50%). REM sleep declines to 25% in toddlers and children, close to adult proportions. Slow-wave sleep (SWS, N3) also emerges in the first 2 years of life and accounts for approximately 30% of total sleep time in toddlers and preschoolers. SWS declines to 20% or less in older adolescents and young adults. The proportion of NREM–REM sleep per cycle also changes across development. The proportions of REM–NREM

do not differ appreciably from early- to late-sleep periods in infants, whereas the length of REM periods increases during each cycle as the night progresses in older children and adults. See Table 5.9.2 for differences between infants and adults sleep.

Sleep cycles are also characterized by multiple, brief arousals throughout the night usually at points of REM/NREM transitions. These physiologic arousals are normative, but can lead to night awakenings when children are unable to return to sleep on their own. Finally, circadian rhythms, responsible for daily variations of alertness, core body temperature, and melatonin secretion, emerge within the first 4 weeks but become more soundly synchronized to day–night cycles by 2 to 6 months (11,12).

Finally, sleep duration decreases with maturation of the central nervous system. See Table 5.9.3 for average sleep durations in children and adolescents (13).

TABLE 5.9.2

DIFFERENCES BETWEEN SLEEP IN INFANTS AND ADULTS

	Infants	Adults
NREM/REM %	50/50	80/20
Ultradian cycle length	50–60 min	90 min
Circadian cycle	Polyphasic	Diurnal
Temporal distribution of NREM/REM during the night	Equi-distributed	First third/last third
Sleep stages	Quiet Sleep (NREM) Active Sleep (REM)	NREM (N1–N2–N3) REM

TABLE 5.9.3

SLEEP DURATIONS IN CHILDHOOD AND ADOLESCENCE

	Mean Nighttime Sleep Duration (hours)	Mean Daytime Sleep Duration (hours)
6 mos old	14.2	3.4
3 yrs old	12.5	1.7
6 yrs old	11	—
10 yrs old	9.9	—
12 yrs old	9.3	—
15 yrs old	8.5	—

SLEEP REGULATION

The sleep–wake cycle is regulated by two core processes, as postulated by Borbely et al. (12). One, defined as process S, is sleep-dependent, homeostatic, and contingent on the amount of time spent awake preceding sleep time plus the accumulated sleep debt; process S increases with wakefulness and decreases with sleep. The second component, process C, is regulated by circadian rhythms, self-

sustained rhythms of approximately 24 hours. Process C is responsible for circadian variations in alertness, activity, and physiologic systems. It is regulated by a combination of internal and external factors. Internal factors include the activity of the suprachiasmatic nucleus (SCN), the body's master clock, and its effects on melatonin secretion, among others. The SCN rhythm is slightly longer than 24 hours in most individuals and must be entrained into a 24-hour pattern by environmental cues, the most powerful of which is the light–dark cycle. Activity and feeding also help maintain circadian stability. The S and C processes operate simultaneously, determining the level of alertness in individuals. While process S progressively increases with time, process C produces two periods of increased alertness, one at the end of the morning, and one in the evening, prior to sleep onset. This latter increase in alertness is responsible for "the second wind," or the sense of increased energy and vigilance most individuals experience in the last part of the day. The relationship between process C and shared social time determines the circadian preference, that is, whether a child or an adolescent is a lark (morningness preference) or an owl (eveningness preference).

ASSESSMENT

Clinicians can assess normal and pathologic sleep subjectively using clinical interviews, questionnaires, and sleep diaries. Objective methods such as actigraphy and PSG can be useful in assessing specific sleep disorders, as shown in Tables 5.9.4 and 5.9.5 (9,14).

CLINICAL INTERVIEW

The use of screening tools increases the detection of sleep disorders and should be included in any evaluation of children even in the absence of sleep complaints (15). The BEARS acronym is a validated screening tool for reminding primary care clinicians to assess the following domains: (1) Bedtime Issues (including insomnia or bedtime refusal), (2) Excessive Daytime Sleepiness, (3) Awakenings/Abnormal Behaviors During Sleep, (4) Regularity or Duration of Sleep, and (5) Snoring (15,16). Routine use of a screening method such as BEARS leads to significant increase in detection of sleep disorders. The BEARS can also be administered as a form; see Table 5.9.5 (7). If sleep problems are reported, a more detailed sleep and medical history should be gathered, along with current medications and a physical examination including a calculation of body mass index (BMI) and an examination of the tonsils. See Table 5.9.6 for content and examples of probing questions for a sleep interview.

TABLE 5.9.4

COMMON RESPIRATORY INDICATIONS FOR POLYSOMNOGRAPHY IN CHILDREN

Suspicion of obstructive sleep apnea (OSA)	Presence of respiratory symptoms (e.g., habitual snoring, witnessed apneas) and associated symptoms (e.g., hyperactivity, enuresis) Any of the above symptoms plus obesity → low threshold for PSG
Low threshold in neurodevelopmental syndromes (high prevalence of sleep-disordered breathing)	For example, Down syndrome, Prader–Willi, Chiari malformation
Low threshold in craniofacial abnormalities, neuromuscular disorders or abnormal chest wall syndromes	For example, Duchenne muscular dystrophy, achondroplasia, craniofacial dysostosis
Post-tonsillectomy in case of:	Moderate to severe OSA at baseline, obesity, craniofacial anomalies, neurodevelopmental disorders
Suspicion of sleep-related breathing disorder in infants who have experienced an apparent life-threatening event (ALTE)	

MONITORING SLEEP AND WAKING BEHAVIOR

Sleep diaries are useful tools for sleep assessment and treatment monitoring and show good reliability with actigraphy for actual sleep start and end (17). The parents and the child should compile a sleep diary daily for 1 to 2 weeks, ideally prior to assessment. In the sleep diary the informants can mark the occurrence of a sleep problem (e.g., sleepwalking or nightmare events) but also indicate multiple sleep behaviors such as sleep duration, sleep-onset latency, nap duration and timing, sleep–wake regularity, and circadian preference. Sleep diaries can be downloaded from the American Academy of Pediatrics (https://www2.aap.org/sections/dbpeds/pdf/sleeplog.pdf). Parental report measures include the Child Sleep Habits Questionnaire (CSHQ) (18) and the Pediatric Sleep Questionnaire (PSQ) (19), both of which are dimensional scales of problem sleep behaviors (bedtime problems, sleep-disordered breathing, etc.). These questionnaires have demonstrated reliability and validity with respect to identifying both behaviorally based and medically based sleep disorders in children aged 2 to 18 years (19) and 2 to 10 years (18,20). Circadian preference can be assessed with the Children's Chronotype Questionnaire (CCTQ), along with a sleep diary (21).

TABLE 5.9.5

BEARS FORM CIRCLE OR HIGHLIGHT ANY QUESTION YOU WOULD ANSWER YES

	Toddler/Preschool (3–5 yrs)	School-aged (6–12 yrs)	Adolescent (13–18 yrs)
1. Bedtime	Does your child have	Does your child have	Does your teenager have

problems	any problems going to bed? Falling asleep?	any problems at bedtime (fights, complaints, fears)? Does your child have difficulties falling asleep?	any problems falling asleep at bedtime?
2. Excessive daytime sleepiness	Does your child seem overtired or sleepy a lot during the day? Does he/she still take naps?	Does your child have difficulty waking in the morning, or seem sleepy during the day or take naps during the day?	Does your teenager have difficulty waking in the morning, seem sleepy during the day or take naps during the day? More than average?
3. Awakenings during the night	Does your child wake up a lot at night? Night terrors? Sleep walking?	Does your child seem to wake up a lot at night? Any sleepwalking or nightmares? Bedwetting?	Does your teenager wake up a lot at night? Does your teenager have trouble getting back to sleep in the middle of the night? Any sleepwalking or nightmares?
4. Regularity and duration of sleep	Does your child have difficulties maintaining a regular bedtime and wake time? (Falling asleep/waking up at different times)	Does your child have difficulties maintaining a regular bedtime and wake time during school days? During weekends? Do you think he/she is not getting enough sleep?	Does your teenager have difficulties maintaining a regular bedtime and wake time during school days? During weekends?
5. Snoring	Does your child snore a lot or have difficulty breathing at night?	Does your child have loud or nightly snoring or any breathing difficulties at night?	Does your teenager snore loudly or nightly? Does your teenager ever stop breathing during the night?

Sleepiness can be assessed using a modified version of the Epworth Sleepiness Scale, the Pediatric Daytime Sleepiness Scale, or the Cleveland Adolescent Sleepiness Questionnaire (22).

PREVENTION AND PARENT EDUCATION

Parents and children should be regularly educated on how to maintain or improve sleep using healthy sleep practices, referred to as sleep hygiene, starting in infancy (7,16,23). Good sleep hygiene practices have been found to be associated with good sleep in children from birth to age 10 (1,23). In order to stabilize circadian rhythms (process C) and regulate sleep drive (process S), children should, as best as possible: (1) maintain a regular sleep–wake schedule both on weekdays and weekends; (2) keep a regular daily schedule, including meals and physical activity; (3) avoid bright light and screen use, including e-readers, for at least 1 hour prior to the target bedtime (to avoid melatonin suppression secondary to light); (4) be exposed to natural bright light in the morning (blinds open at wake-up time, walking

to school if possible) to stabilize circadian rhythms; and (5) schedule age-appropriate or strategic naps when indicated. Consistency of wake-up time is more relevant than bedtime for circadian entrainment and parents should enforce wake-up time within 2 hours on weekends compared to weekdays. Clinicians should also educate parents and children regarding appropriate sleep need requirements by age and suggest that an age-appropriate amount of sleep should be scheduled in the child's day, as for any other fundamental activity. This is increasingly challenging, as most adults engage in poor sleep hygiene.

Positive sleep associations can be promoted by: (1) encouraging an age-appropriate and consistent bedtime routine; (2) avoiding sleep-incompatible or arousing activities in bed during the day and at bedtime, including watching TV, computer use, doing homework or drinking of caffeinated beverages; and (3) limiting parental interaction with the child prior to sleep onset. A soothing and enjoyable bedtime routine creates positive associations with sleep-time and sets the tone for both body and mind to prepare for sleep. Similarly, avoiding stimulating or unpleasant activities in bed eliminates the association between bed and arousing activities. For this reason, ideally, the bedroom should not be routinely used for timeout or other negative consequences in pre-school age children and toddlers. Suitable bedtime routines change according to the child's age and can include bathing, cuddling, or reading a story. Ideally, bedtime routines should be consistent, repeating in the same order and lasting no longer than 30 minutes. Independent sleep onset should be encouraged as early as possible, and is achieved by limiting or removing parental interaction with the child prior to sleep (see insomnia). The use of a transitional object (a blanket, a stuffed animal) can be used to redirect sleep associations in children after 6 months of age, when the child does not require night feedings.

Use of caffeine or any other sleep-impacting substances, including nicotine, marijuana or other illicit drugs, should be assessed, as their effects on sleep are usually underestimated by parents and children. Caffeine use has been understudied in adolescents but appears to be associated with chronic sleep loss, worse academic functioning, nicotine use, and higher risk of other substance use (2).

CLASSIFICATION OF SLEEP DISORDERS IN CHILDHOOD

Sleep disorders are differently represented at different ages. During infancy, difficulties falling asleep independently and night awakenings are the most common problems. By contrast, toddlers and children also present sleepwalking, obstructive sleep apnea (OSA) and nightmares, while adolescents tend to display insufficient sleep hygiene and circadian rhythm disorders.

TABLE 5.9.6

SLEEP INTERVIEW

History of Sleep Problems		Example Probing Questions	Comments
	Onset, timing and course	What is the frequency of the symptom in terms of events per week or per night? What has been its course (stable, worsening, improving)?	
Functioning	Excessive daytime sleepiness	Does the child fall asleep in class or watching TV? Does the child struggle to wake up?	Excessive daytime sleepiness is always pathologic in children
	Social and family dysfunction	Is the child embarrassed to sleep at a friend's house because of the sleep problem? Is the child's sleep problem negatively affecting parents?	Child sleep problems are associated with high degree of parental stress
Sleep–Wake Schedule	Bedtime and wake-up time sleep duration	What is the usual bedtime and rise time?	Sometimes parental expectations do not match developmental sleep needs
	Time and circumstances needed to fall asleep	Does the child fall asleep easily or need parental intervention or presence?	
	Awakenings: How frequent? How long?	Does the child signal to parents? Or is she able to self-soothe if she wakes up at night? What is the parents' response?	
	Naps and their duration		Naps are developmentally appropriate until ages 4–5. Naps after this age may indicate excessive daytime sleepiness
	Regular schedule on schooldays vs. vacation days	What is the sleep–wake schedule on school days and vacation days?	More than 2 hrs difference can indicate sleep deprivation and/or circadian rhythm disorder
Bedtime Routine		Does the child have a regular bedtime routine? Is it soothing? Is there screen use within 1–2 hrs of sleep time? Are bedtime rituals present?	Regular bedtime routine is associated with better sleep; screen use within 1 hour of

			sleep onset can worsen sleep and decrease melatonin secretion
Bedtime Environment	Consistent? Dark? Quiet? Co-sleeping? TV or computer in the room? Cellphone use overnight?	What are the sleeping arrangements? With whom does the child share a room or bed? Does the child fall asleep in his bed? Is co-sleeping a choice or a consequence of inability to set limits?	TV in the bedroom is associated with worse sleep in children. White noise machine, earplugs, blinds or eye-masks should be considered if sleep environment is inadequate
Sleep Review of System	Snoring/gasping; excessive movements during sleep; restless legs syndrome; abnormal behaviors; enuresis; nightmares; teeth clenching	Is snoring prominent, habitual, even in absence of a cold? Are pauses in breathing audible? Is the child restless during sleep? Have the parents noted abnormal behaviors or movement during sleep? Sleepwalking? Does the child endorse "funny" "strange" feelings in her legs before sleep time? Does she say that her legs need to kick at night?	

Whereas there was only partial agreement for the criteria of sleep disorders among different classification systems in the past, recent revisions have strived to harmonize diagnostic criteria. Currently, there is fair concordance in sleep disorder classifications and criteria between *The International Classification of Sleep Disorders*, 3rd Edition (ICSD-3) (24) and the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) (25), even if the ICSD-3 contains a greater level of detail, because it is geared toward sleep specialists. The major classification changes in DSM-5 and ICSD-3 are related to the collapse of different insomnia diagnoses into a single entity, defined as chronic insomnia, and the adoption of unique criteria for both adults and children, with age-appropriate specifiers. This has led to the possibility of diagnosing DSM-5 insomnia in children and the elimination of the "behavioral insomnia of childhood" diagnosis from ICSD-3.

Currently, both nosologies include sections on (1) insomnia, (2) sleep-related breathing disorders, (3) hypersomnias, (4) circadian rhythms disorders, (5) parasomnias, (6) sleep-related movement disorders; see Table 5.9.7. The other clinically relevant change in DSM-5 is that sleep disorders and psychiatric disorders can be diagnosed concurrently. For example, the diagnoses of depression and insomnia can both be assigned if the insomnia does not appear to be simply secondary to the depression. This change in DSM-5 reflects the awareness that sleep

disorders have an impact on the course and severity of psychiatric conditions and that they warrant their own attention and treatment.

For younger children, the Diagnostic Classification: Zero to Three, Revised (DC 0–3R) (26) can also be used. DC 0–3R is a multiaxial nosology of mental disorders developed specifically for use in infancy and early childhood. DC 0–3R provides several opportunities to classify sleep problems, either as a primary entity or as a symptom of another Axis 1 disorder such as traumatic stress disorder, adjustment disorder, regulatory disorder, anxiety disorder, or mood disorder. This classification is currently being revised.

TABLE 5.9.7

MAIN CATEGORIES OF SLEEP DISORDERS IN DSM-5 AND ICSD-3

Category	Description
Insomnia	• Persistent difficulties sleeping • Adequate opportunity for sleep • Daytime impairment (e.g., chronic insomnia)
Sleep-related breathing disorders	• Irregular breathing during sleep, possibly accompanied by sleep disruption (e.g., obstructive sleep apnea)
Hypersomnolence disorder and narcolepsy	• Excessive daytime sleepiness, in spite of adequate sleep (e.g., narcolepsy, hypersomnolence disorder)
Circadian rhythms disorders	• Misalignment of circadian rhythms and social requirement (e.g., delayed sleep phase)
Parasomnias	• Abnormal physical and emotional experiences during sleep or sleep–wake transitions (e.g., sleepwalking, nightmares)
Sleep-related movement disorders	• Presence of movements that delay sleep onset or disrupt sleep (e.g., restless legs syndrome)

Insomnia

General Features

Bedtime resistance, night awakenings, difficulties falling asleep or remaining asleep are the main symptoms of insomnia in childhood. Difficulty falling asleep without caregiver intervention, for example, a parent sitting or lying next to the child, is also considered a feature of pediatric insomnia. This was defined as sleep-onset association type insomnia in prior classifications (16). Bedtime resistance and bedtime "stalling" (calling out, getting out of bed, fighting bedtime routines) was previously described as limit-setting type insomnia (16). Other than nighttime problems, children with insomnia can display behavioral and cognitive problems, including sleepiness, tiredness, irritability, aggression, hyperactivity and social withdrawal (22). Pediatric insomnia is common and can begin at any age, although it is not usually diagnosed before 6 months of age, as nocturnal feedings and irregular sleep patterns are typical in infants (22) (ICSD-3). In community samples of infants,

toddlers and preschoolers, the prevalence rates of insomnia are 20% to 30% (16). In older children, insomnia prevalence ranges between 10% and 30%, depending on criteria stringency. In European and American adolescents the prevalence of insomnia ranges between 6% and 11% (22). In children with psychiatric disorders or developmental delays, the prevalence of insomnia can be substantially higher, for example, 80% among children with autistic spectrum disorder have some difficulties sleeping (4,27).

The pathophysiology of insomnia remains unclear, but current models support a combination of behavioral, developmental, familial, and temperamental risk factors. Behavioral aspects include parental handling, especially for younger children. Sleep-related hypervigilance or hyperarousal, along with negative sleep associations are common elements of insomnia across the lifespan. The process of decreasing vigilance and/or extinguishing negative associations through relaxation, predictability of positive bedtime routines, and extinction of dysfunctional associations (such as parental presence) are common treatment strategies (22).

Insomnia needs to be distinguished from other sleep or psychiatric disorders. Delayed sleep phase, OSA, restless legs syndrome, and primary mood or anxiety disorders should be considered in the differential diagnosis when assessing for insomnia (5). For adolescents, along with delayed sleep phase disorder, volitional sleep restriction should also be considered.

Behavioral strategies are the first line of treatment for pediatric insomnia. However, most of the literature has focused on infants and preschoolers, and there is a lack of well-established treatments for older children, adolescents, and children with special needs (22,28). Use of medications should be considered only as an add-on after an appropriate behavioral plan has been implemented (29). In younger typically developing children, behavioral treatments are highly effective; 80% of children have a clinically significant positive response in terms of sleep latency and night awakenings that is maintained for up to 6 months (23) with large within-subject effect sizes (28). Unmodified extinction (ignoring all negative behaviors after lights out until a set time in the morning, unless the child is in danger or ill), graduated extinction (brief parental checks with decreased frequencies after lights out, accompanied by ignoring all negative behavior) and prevention/parent education are considered established and effective treatments for young children. Extinction strategies can be emotionally challenging for parents who typically resist implementing them. Parents should be reassured that these behavioral interventions have not been associated with negative outcomes (28). While there are limited studies on cognitive-behavioral interventions for older children and adolescents, it seems plausible to use them as well, pending controlled studies (28). Stimulus control is considered standard of care for insomnia in adults and targets the associations between bed and negative feelings and behaviors associated with insomnia. It involves going to bed only when sleepy, and leaving the bedroom when

unable to sleep for extended times (20 to 30 minutes), engaging only in boring activities in dim light, for example, reading a boring book. Additionally, the bed should be only used for sleep. As the child or adolescent engages in stimulus control, she starts associating her bed with feeling sleepy, rather than with frustration or the arousal secondary to sleep-incompatible behaviors, such as watching TV or texting. Both the patient's understanding of these principles and parental support and monitoring are crucial for success. Often, phone and computer removal from the bedroom is necessary for effective implementation. Relaxation is also considered standard of care and includes classic progressive muscle relaxation and diaphragmatic breathing that should be mastered by the child during the day, prior to nighttime use. Other components of cognitive-behavioral therapy for insomnia that can be implemented are sleep restriction/bedtime fading and cognitive restructuring, when clinically and developmentally appropriate (22,30).

The U.S. Federal Drug Administration has not approved any medications for the treatment of pediatric insomnia and most of the guidelines for pediatric insomnia are based on expert consensus rather than randomized controlled trials (31). Indications for pharmacotherapy include acute stressors or medical illness, and lack of response to or parental inability to conduct behavioral intervention. Contraindications include potential negative interactions, for example, presence of other sedating medications, alcohol or illicit drug use. Other sleep disorders such as OSA and restless legs syndrome should be ruled out, as medication might exacerbate and/or mask the primary condition. The choice of medication should be based on clinical characteristics (e.g., age, sleep-onset vs. maintenance insomnia, comorbidities, other medications used) and should minimize side effects. Parents should be educated on goals, side effects (e.g., possible "paradoxical" effects such as stimulation and disinhibition, tolerance), optimal duration and possible modifications (nightly vs. intermittent use) of medication treatment. Attempts to discontinue the agent should be made regularly. Gradual taper is preferred to decrease recrudescence and symptomatic rebound. Melatonin is often considered a first-line agent for pediatric insomnia, given its efficacy and relatively benign short-term side-effect profile both in neurotypical children and children with psychiatric conditions. Melatonin doses range between 1 and 3 mg, with even lower doses recommended for treatment of delayed sleep phase (32). Alpha-2 agonists such as clonidine or guanfacine are also widely used by pediatricians and child psychiatrists and can have a role in treating insomnia in children with attention-deficit/hyperactivity disorder (ADHD) given their indications for this condition (31). Risk of rebound hypertension on abrupt discontinuation, narrow therapeutic index, and possible onset of tolerance for sedating effects should be considered, especially for clonidine (31). Antihistamines such as diphenhydramine are the most commonly used sedatives in pediatric practice, but their chronic use for insomnia is not supported by empirical data, secondary to lack of demonstrated efficacy, rapid tolerance with consequent dose escalation and

anticholinergic, histaminergic, and adrenergic side effects (31). Other agents might be specifically indicated for insomnia with specific comorbidities, for example, long-acting benzodiazepines such as clonazepam for comorbid anxiety disorders or disorders of arousal (31).

Sleep-Related Breathing Disorders

The physiology of the respiratory system and ventilatory control changes dramatically during sleep. This determines the occurrence of specific breathing disorders during sleep, such as sleep-related hypoventilation or central sleep apnea. Since these potentially fatal disorders are usually diagnosed and treated by sleep specialists or pulmonologists, only OSA will be presented, given its high prevalence and impact on children and adolescents.

Obstructive Sleep Apnea

OSA is a well-known but still under recognized sleep disorder and should be suspected in any child who snores. The prevalence of OSA is 1% to 5% in the general pediatric population but likely much higher in obese children and children with medical or neurodevelopmental conditions and habitual snoring (33). However, as parents get used to their children snoring, they tend not to report it, unless specifically probed. Notably, primary snoring, even in the absence of OSA, is associated with symptoms and consequences similar to OSA (34).

Clinically, symptoms of OSA include chronic snoring, labored breathing, gasping, or choking during sleep, apneas (breathing pauses) witnessed by parents and/or frequent arousals in a child with chronic snoring. Nocturnal enuresis often accompanies pediatric OSA. Excessive daytime sleepiness is less prominent in children than in adults, but children with OSA are prone to develop psychiatric symptoms mimicking ADHD, irritability, and behavioral problems (7,33).OSA requires PSG for definitive diagnosis and assessment of severity. Polysomnographycally, it is identified by the presence of apneas, hypopneas and brief cortical arousals during sleep, secondary to intermittent upper-respiratory obstructions. In children and adolescents, the upper airway obstruction is often secondary to enlarged tonsils and adenoids, but obesity, craniofacial and muscular abnormalities can also determine or worsen OSA. Chronic snoring and OSA should be routinely screened in children with ADHD; PSG is indicated for detection of OSA in typical children in the presence of clinical symptoms. Clinicians should have a low threshold for requesting a PSG whenever sleep-disordered breathing is suspected or when evaluating children with neurodevelopmental conditions such as Down syndrome, Prader–Willi, or neuromuscular diseases. See Table 5.9.4 for respiratory indications for PSG.

Consequences of untreated OSA include cardiovascular, growth, cognitive, and behavioral abnormalities (33). Cognitive deficits associated with OSA include lower scores on objective and subjective measures of general intelligence, attention, memory, and executive function (33).

Adenotonsillectomy is the primary treatment for OSA in children. Successful treatment of OSA typically results in improvements in behavioral problems and cognitive functions, though residual OSA after adenotonsillectomy is common. Post-adenotonsillectomy OSA is found in up to a third in low-risk populations and up to two-thirds in obese children (33). Nasal steroids can be considered for mild cases.

Parasomnias

Parasomnias are disorders characterized by the recurrence of undesirable behaviors or emotions during sleep or at sleep transitions. Parasomnias are classified as NREM parasomnias, REM parasomnias, or other parasomnias. Examples of NREM parasomnias or disorders of arousal are sleepwalking and sleep terrors. Examples of REM-related parasomnias are nightmare disorder, REM behavior disorder, and recurrent sleep paralysis; enuresis is considered an "other parasomnia" (24). The concomitant presence of features of wakefulness and sleep at the same time, such as locomotory behavior during sleep, is a key feature of parasomnias. This section covers disorders of arousals (NREM parasomnias) and nightmare disorders, given their high prevalence in children. Enuresis is covered in Chapter 5.12.

Disorders of Arousal, NREM Parasomnias

The two most common, and clinically relevant, NREM parasomnias in childhood are sleep terrors and sleepwalking. Essential features are presence of arousal and motor behaviors and/or significant autonomic activation while the person is still asleep or only partially aroused (35). Complete amnesia is usual, unless the individual wakes up during the event. They are associated with risk for serious injury (36).

During sleepwalking episodes, the child leaves the bed and wanders and can engage in potentially dangerous activity such as leaving the house or cooking. The child appears confused, with limited response to verbal or physical stimulation and emits no or reduced verbal responses (usually basic words). Occasionally, the family becomes aware of sleepwalking behaviors when the child wakes up in the morning, not in bed. Episodes usually last a few minutes but can occasionally last up to half an hour.

Night terrors are characterized by a sudden arousal, accompanied by loud screaming, possible simple vocalizations, and autonomic activation with tachypnea, tachycardia, and diaphoresis. The child may appear glassy-eyed, staring without seeing, and unresponsive to visual or verbal cues. Sleep terrors are usually briefer,

lasting from 30 seconds to 5 minutes, but they occasionally can be longer. Frequency of episodes ranges from a few episodes a year to daily. Episode frequency tends to decrease with age.

NREM parasomnias are common. The prevalence of sleep terrors has been reported in up to 34% in children below age 2, and lifetime episodes of sleepwalking have been reported in up to 29% in older children with a peak between ages 6 and 12 (35,36). These disorders persist in 3% to 4% of adults (35). Boys and girls are equally affected (35,36). Familial aggregation has been consistently reported. Pathophysiologic overlap among disorders of arousal is suggested by the emergence of later sleepwalking in up to a third of young children with sleep terrors (36). Both kinds of episodes are triggered by the same factors, including sleep deprivation, noise, fever, medications, and sleep disruptions in general, including sleep-related breathing disorders (36).

Electroencephalographically, sleep terrors and sleepwalking arise from SWS (N3), and during the events, the individual is cortically asleep, despite motor or vocal behavior and apparent distress. This explains the amnesia and lack of mentation (no dreaming content) if awakened, inconsolability, and the temporal distribution (emergence in the first third of the night when N3 is maximally represented).

The differential diagnosis of NREM parasomnias includes nightmares and seizure disorders, specifically nocturnal frontal lobe epilepsy. Nightmares are more frequent in the last part of the night and are associated with vivid dream imagery, a fully alert, frightened and oriented youngster, and recollection of the episode in the morning. Nocturnal seizures are usually briefer than parasomnias, lasting often less than 2 minutes, can present multiple times per night, do not cluster in the first third of the sleep time, and behaviors are often highly stereotyped (35). A PSG is indicated when nocturnal epilepsy is suspected, or when episodes are extremely frequent, atypical or violent or might be associated to OSA. See Table 5.9.8 for nonrespiratory indications for PSG.

TABLE 5.9.8

COMMON NONRESPIRATORY INDICATIONS FOR POLYSOMNOGRAPHY AND MULTIPLE SLEEP LATENCY TEST IN CHILDREN

Evaluation of hypersomnolence and narcolepsy	Unexplained excessive daytime sleepiness should be assessed with PSG followed by multiple sleep latency test (MSLT)
Parasomnias	In presence of frequent or potentially injurious parasomnias, to differentiate parasomnia from nocturnal epilepsy, in case of enuresis, or if there is suspicion for parasomnia comorbid with sleep-disordered breathing or periodic limb movement disorder
Suspicion for periodic limb movement disorder and possibly for supportive	For children with RLS who also complains of poor sleep or those symptoms suggestive of periodic limb movement disorder

data for restless leg syndrome (RLS)

The basic treatment for parasomnias includes child and family reassurance, education, and safety measures. The family should be informed that episodes are usually transient, not serious, and in most cases require no specific pharmacologic intervention. Since sleep deprivation and/or irregular schedules might trigger episodes in predisposed children, parents should be advised of the importance of strict sleep hygiene and sufficient amounts of sleep for the child's age. An after-school nap may be suggested to reduce night N3 intensity and reduce propensity for episodes. Sleep terrors and sleepwalking have a potential for injuries and safety should be addressed. See Table 5.9.9 for safety measures for NREM parasomnias. A possible behavioral approach to frequent episodes of parasomnias is to establish scheduled awakenings. Parents are instructed to monitor the time of the episodes through a sleep diary and to briefly awaken the child approximately half an hour prior to the expected episode. While often successful, this technique might also trigger more events. When the episodes do not respond to sleep hygiene, are frequent or severe with concern for dangerous activities, a low dose of long half-life benzodiazepine, for example, clonazepam, can be used at bedtime for 2 to 3 months and then tapered slowly, monitoring for reoccurrence upon discontinuation.

Nightmares

Dreams are normally reported by children after age 3 (37) and nightmares shortly thereafter. Whereas a standard definition is still lacking, nightmares can be broadly defined as dreams characterized by intense negative emotions such as fear, but also anger, disgust, or sadness, which awaken the individual from sleep (38). Disturbing dreams or "bad dreams" are similar to nightmares but do not interrupt sleep. There is a phenomenologic and likely qualitative continuity between nightmares and disturbing dreams. Clinically, both require attention if they are associated with waking emotional distress. Nightmares mostly occur during REM sleep and thus are considered an REM parasomnia. After waking up from a nightmare, the child is often scared but awake, oriented and able to recount the dream content. This helps differentiate them from sleep terrors. Because REM sleep occurs most commonly in the latter third of the night, nightmares generally are noted in the early morning hours, after 2:00 AM. For preschool children, nightmares often include images of monsters and frightening animals; for older school-age children, nightmares typically include more usual human imagery including being injured, lost, or abandoned. If nightmares are frequent, they can be a source of bedtime resistance. Nightmares and disturbing dreams are associated with both acute and posttraumatic stress disorders, anxiety disorders, and suicidal ideation, even when controlling for depression in children and adolescents (39). They are also associated with sleep disorders including sleep

deprivation and other parasomnias (38,39). Nightmares and disturbing dreams are common in children and adolescents, up to three to four times the rates reported for adults (38). At ages 3 to 5, 10% to 50% of children report having experienced disturbing dreams. Prevalence rises with age and peaks at ages 10 to 12, with frequent nightmares reported by up 44% (38,39). Disturbed dreams are approximately equally present in boys and girls but toward early adolescence, they become more common in girls and less common in boys (38,39).

TABLE 5.9.9

SAFETY MEASURES FOR SLEEP TERRORS AND SLEEPWALKING

Assess for injuries or dangerous behaviors	Injuring self or others? Falling? Leaving the house? Using the stove? Inappropriate ingestion of food or medications? Aggressive behaviors?
Establish safety	Parent notification measures, e.g., bells/alarm on the door Secure front door Remove sharp objects Cover sharp obstacles Barricade and/or cover windows Lock firearms and medications Mattress on the floor if indicated Manage sleepovers and college living arrangement (ideally first floor dorm room for frequent episodes)

Although treatment of nightmares in adults has progressed (40), limited interventions address this condition in children (39). If nightmares are frequent or distressing, the presence of possibly undisclosed trauma and/or other concurrent anxiety symptoms, including separation anxiety should be explored. Imagery rehearsal therapy appears to be the most promising treatment both in children and adolescents (39). During treatment, the child is invited to modify the content of his most recent nightmare to something not distressing, and then visualize and rehearse (cognitive intervention and exposure) the new imagined version while in a state of relaxation (behavioral intervention) (41). The child can also use drawings rather than mental imagery, if developmentally appropriate (39). Although some research has been done on the treatment of nightmares using pharmacologic agents, insufficient evidence supports such treatments for children (39).

Hypersomnolence Disorders and Narcolepsy

Hypersomnolence (excessive daytime sleepiness) is the main characteristic of several sleep disorders. DSM-5 classifies syndromes with primary hypersomnolence into two groups: (1) hypersomnolence disorder and (2) narcolepsy. ICSD-3 differentiates narcolepsy into two subtypes. ICSD-3 “narcolepsy type 1” requires

demonstration of orexin/hypocretin deficiency or presence of cataplexy. Hypersomnolence accompanied by objective measures of sleepiness via MSLT and/or presence of sleep-onset REM periods is defined as "narcolepsy type 2." In the ICSD-3, other conditions characterized by hypersomnolence are classified as other disorders. These include idiopathic hypersomnia and hypersomnia associated with a mental disorder. This section follows the DSM-5 classification.

Hypersomnolence Disorder

Historically, hypersomnolence was a key feature of narcolepsy, but starting from the late 1970s, the diagnosis of idiopathic hypersomnia became attached to excessive sleepiness not associated to narcolepsy (42).

The main feature of hypersomnolence disorder is excessive daytime sleepiness, in the absence of substantial sleep deprivation. Clinically, patients usually complain of excessively long night sleep, restorative sleep, and need for frequent naps or dozing off. They can also struggle with awakening in the morning, or present prolonged confusion upon awakening (i.e., sleep drunkenness or sleep inertia). Associated features can be manifestations of autonomic dysfunction such as headache, cold extremities, temperature dysregulation, digestive problems, and cognitive symptoms such as attention and memory problems and mental fatigability (42). Pathophysiologic, genetic, traumatic or immunologic hypotheses have been proposed but mechanisms of the disorder remains unclear (42). Prevalence is between 0.5% and 1% in the general population (25,42) with onset generally beginning in adolescence or young adulthood and usually a stable course (42). Psychiatrically, hypersomnolence disorder often accompanies affective illnesses, especially depressive episodes including unipolar and bipolar types; the presence of a mental disorder can be specified in DSM-5. The diagnostic process is complex and patients should be referred to a sleep specialist for a conclusive diagnostic workup including actigraphy, PSG and MSLT, and for treatment. Differential diagnoses include insufficient sleep syndrome, narcolepsy, OSA, delayed sleep phase disorder, or medical conditions such as hypothyroidism (42).

Narcolepsy

Clinically, narcolepsy is characterized by severe and chronic hypersomnolence and brief intrusions of REM sleep–like states during wakefulness. These REM sleep intrusions are responsible for most of the symptoms of narcolepsy, namely cataplexy, sleep paralysis, and hypnagogic hallucinations. Cataplexy is pathognomic for narcolepsy and presents as a sudden loss of peripheral muscle tone, usually provoked by strong affect, often positive, such as laughter. The face and neck are often involved and cataplexy can present as slurred speech. Cataplexy reflects the muscle

atonia of REM sleep. In children, cataplexy can also present as long-lasting periods of decreased muscle tone, unsteady gait, grimacing, and tongue protrusions (43). Cataplectic attacks are brief, rarely lasting more than 1 to 2 minutes, with immediate and complete recovery. Attacks may occur only a few times a year or as frequently as many times a day. Consciousness and memory remain intact, if the child remains awake. Sleep paralysis is characterized by inability to move at sleep–wake transitions. The paralysis lasts for seconds to a few minutes and is another manifestation of REM sleep atonia incursion into wakefulness. Similarly, REM-related mentation (dreaming) can intrude during wakefulness at sleep–wake transitions as hypnagogic or hypnopompic hallucinations. They often present as complex hallucinations (visual and auditory), rarely lasting longer than 1 to 2 minutes. Fragmentation of nocturnal sleep is also common but brief naps are usually refreshing. Obesity and depression are also often associated features of narcolepsy (43).

Narcolepsy affects about 1 in 2,000 people in the general population. Onset is usually in the second decade, although onset can be earlier. The diagnosis is often delayed 5 to 15 years and approximately half of all individuals with narcolepsy remain undiagnosed (43). The diagnosis is established objectively with PSG and MSLT. The form of narcolepsy associated with low cerebrospinal fluid level of orexin/hypocretin is often accompanied by cataplexy and generally has more severe symptoms (43). Other forms of narcolepsy present with PSG and MSLT abnormalities diagnostic of narcolepsy, without cataplexy and/or low orexin/hypocretin levels. These forms may be phenotypically similar disorders with different etiologies and pathogeneses (43). Low levels of orexin/hypocretin and cataplexy are usually associated with loss of orexin-producing neurons. Genetic factors play a role in this degenerative process; more than 98% of individuals with low orexin/hypocretin and/or cataplexy are positive for the human leukocyte antigen (HLA)DQB1*06:02, which is present in 12% to 30% of the general population (43). Polymorphisms of other genes affecting immune function have also been associated to this form of narcolepsy. Autoimmune processes, secondary to infections but also to vaccinations, have been proposed as mechanism of neuronal destruction (43). The pathogenesis of forms of narcolepsy not associated with low orexin/hypocretin is unknown (43).

The treatment of narcolepsy is based on a combination of behavioral and pharmacologic approaches. A regular sleep–wake schedule is strongly advised for children and adolescents with narcolepsy. Regular meal times and physical activity should also be encouraged at an early stage to avoid weight gain, which can be severe. Additionally, routine naps of 20 to 30 minutes are generally recommended to increase daytime wakefulness and psychomotor performances. This can be difficult during school hours, but the gym or infirmary can be used. The adolescent naps for 20- to 40-minute periods, awakening refreshed. The cycle is repeated again within 2

to 3 hours. This refreshed feeling contrasts with the disorientation and persistent fatigue associated with hypersomnolence disorder secondary to other causes.

Pharmacologically, stimulant medications are used most commonly for treating excessive daytime sleepiness, and venlafaxine and tricyclic antidepressant medications for cataplexy. Sodium oxybate (sodium salt of gamma-hydroxybutyrate) is effective for both hypersomnolence and cataplexy and in prepubertal children with orexin/hypocretin deficiency can improve obesity, normalize sleep, wake, and cataplexy by itself (44). Sodium oxybate can only be prescribed by sleep specialists because of the risk of diversion and is usually reserved for severe cases.

Patients with narcolepsy usually adjust poorly to their disorder. They exhibit problems in school and in social relationships, thus behavioral management, emotional and psychosocial support, and counseling are essential components of treatment.

Circadian Rhythm Sleep Disorder, Delayed Sleep Phase Type

As mentioned in the section on sleep regulation, circadian rhythms are one of main physiologic systems which regulate sleep–wake cycles. When individuals fall asleep and wake up naturally roughly at the socially expected times, they are considered to have a normal sleep phase. When the sleep and wake-up times occur earlier than socially expected, for example, 7 PM to 3 AM, the sleep phase is defined as "advanced." Conversely, when sleep and wake-up times occur later than socially expected, for example, 3 AM to 11 AM, the sleep phase is "delayed." At times, this misalignment between endogenous rhythms and expected sleep–wake schedule causes social or academic problems, becoming a circadian rhythm disorder.

Development and social demands both affect circadian rhythms and melatonin secretion timing, and most adolescents naturally experience a sleep phase delay, that is, they tend to fall asleep and wake up later than during childhood and often later than expected or required. Clinically, the adolescent complains of being unable to fall asleep and struggles to awake in the morning. Absences and tardiness or dozing off in class are common associated features. As the adolescent stays up late and arises early for school, he tends to accumulate sleep debt and, as a consequence, he often "sleeps in" or does "sleep marathons" on weekends to catch up. This lack of regularity reinforces and worsens the problem, causing a perpetual social jetlag.

Delayed sleep phase disorder prevalence is estimated to be greater than 7% in adolescents (25). Pathogenesis is multifactorial. Delayed sleep phase has been associated with polymorphisms of genes regulating circadian rhythms such as *Per3*, inappropriately timed light exposure, abnormal light sensitivity and social gains, such as unsupervised time for adolescents (7,24).

Differential diagnoses include narcolepsy, given the excessive daytime

sleepiness, and insomnia. However, while individuals with insomnia struggle to fall asleep in most circumstances, adolescents with delayed sleep phase report no difficulties in their sleep patterns when allowed to follow their natural schedule. This can be clarified by asking about their sleep during vacations, sleep during weekends, and asking about circadian variation (do they consider themselves night owls?). Questionnaires, such as the CCTQ, show eveningness preference and a 2-week sleep diary often shows the delayed sleep-onset and extremely delayed wake-up times on weekends. Once a phase delay syndrome is chronic and persistent, phase advance methods of resetting the biologic clock may be necessary. Behavioral methods include strict adherence to sleep hygiene, avoidance of light emitting devices for at least 2 hours prior to scheduled sleep time (as this can cause further phase delay), and avoiding more than 2 hours discrepancy in wake-up time between weekdays and weekends. Ideally, phones and other electronic devices use should be restricted at night. Bright light exposure after natural awakening and low-dose melatonin (0.5 to 1 mg 6 to 4 hours prior to bedtime) are commonly used as chronotherapeutic agents (6,45).

Restless Legs Syndrome/Willis–Ekbom Disease

RLS is a neurologic disorder presenting with sensory-motor symptoms, usually creepy or crawling sensations in the extremities and an urge to move the legs usually relieved by movement. The sensations and the urge to move are more prominent or only present in the evening and are exacerbated by immobility, thus interfering with sleep initiation and maintenance. While the sensory component often accompanies the syndrome, only the urge to move the legs and the other associated features are required. Difficulty falling asleep is a major consequence of RLS along with fatigue, inattentiveness, or sleepiness. Simple questions such as “Do your legs want to kick at night?” and “Do your legs bother you at night?” can be good screening probes for the disorder. The pediatric prevalence of RLS is 2% to 4% in the United States, United Kingdom, and Turkey; moderate to severe RLS was found in 0.5% to 1% of children (24). Childhood RLS is often misdiagnosed as growing pains, limiting access to appropriate treatment. On PSG, during sleep, patients with RLS often show periodic, stereotyped jerks, which are defined as periodic limb movements and can be associated with further sleep disruption. RLS is highly familial, with recent adult studies showing familial rates up to 77% in early-onset cases (46); multiple gene variants have been associated with the disorder in genome-wide studies (47). The pathophysiology of RLS is still unclear but likely related to iron and dopamine metabolism. Iron is a cofactor for tyrosine hydroxylase, which is essential for dopamine synthesis. Thus, ferritin, a measure of iron storage, should be routinely assessed in children with RLS. Oral iron supplementation should be considered for ferritin below <50 mcg/L (47). Adult RLS responds to dopaminergic agents and an

abnormal dopaminergic system may be responsible for the association between RLS and ADHD; approximately one-quarter of individuals with RLS have attention problems and conversely, 13% to 35% of individuals with ADHD meet criteria for RLS (46). For children, iron supplementation and nonpharmacologic treatments are indicated for mild cases. Moderate to severe cases should be referred for medication trials in the setting of long-term specialty care (46).

Disordered Sleep in Psychiatric Conditions

Less information about sleep disorders in children and adolescents with medical and psychiatric conditions is available than for adults. However, the last decade has seen long overdue surge of interest in pediatric sleep disorders. It is becoming evident that sleep disturbances in childhood are common, associated with a wide range of psychopathologies, and represent a risk factor for the development of future psychiatric disorders (1).

Children who live in institutions are reported to have short sleep periods, repeated nighttime awakenings, and phase delay disorders. Children with neurodevelopmental disorders such as autism experience shorter sleep duration, frequent night awakenings and difficulties falling asleep, possibly secondary to melatonin secretion abnormalities (1). Extensive research has demonstrated the association between ADHD and sleep disturbances, although the mechanisms for this association remain unclear (1,48). Children with ADHD often struggle with difficulties falling asleep, RLS, OSA, and periodic limb movements. Objectively, they are more likely to have lower efficiency, more stage shifts, and higher number of apneas or hypopneas, and they tend to have variable sleep–wake schedules (48).

Sleep disturbances, including insomnia, hypersomnia, and nightmares may be important indicators of depression severity and suicidality in children and adolescents (49). Polysomnographycally, youth with depression also display short REM latency, a biologic marker for depression in adults. However, other indicators of disturbed sleep present in adults with depression, including disruptions of sleep-related endocrine regulation, have not been found consistently in children and adolescents (50,51). Sleep extension and circadian manipulation (phase advance) have been considered possible adjunctive treatments for juvenile depression.

So far, limited research has focused on sleep in children and adolescents with psychotic disorders, although difficulties sleeping may predict psychosis onset in high-risk adolescents/young adults. Additionally, the extent of sleep problems was found to correlate with decreased thalamic volume (1), a key brain region involved in sleep. An association between psychotic symptoms at puberty and nightmares and sleep terrors during childhood has also been found (1).

Sleep disturbances have been consistently connected with anxiety disorders in youth, and often interpreted as secondary to anxiety. Conversely, longitudinal studies

have shown that sleep disturbances are often more predictive of later anxiety than vice versa (1).

Finally, poor sleep is associated with increased substance use and risk-taking behaviors; specifically, sleep deprivation can compromise self-regulation and reward-related behaviors, and most substances, including alcohol, exert deleterious effects on sleep–wake cycles and sleep architecture, potentially leading to a vicious cycle. Finally, most psychotropic medications, including serotonin reuptake inhibitors and stimulants, negatively affect sleep or circadian rhythm and require close monitoring.

In closing, more research continues to be needed to better understand the associations and interactions of sleep disturbances with psychopathology. Delineating the underlying mechanisms of these associations will inform causal influences which may have direct implications for therapeutics across a wide spectrum of disorders and functioning.

5.10 SOMATIZATION IN CHILDREN AND ADOLESCENTS

CHAPTER 5.10 ■ FUNCTIONAL SOMATIC SYMPTOMS AND DISORDERS

JOHN V. CAMPO, MARY LYNN DELL, AND GREGORY K. FRITZ

INTRODUCTION

The biomedical model, a central tenet of Western medicine, maintains that the subjective suffering of patients, most commonly described as *illness*, is best understood as a consequence of demonstrable biophysical or biochemical abnormalities at the intracellular, intercellular, organ, organ system, and/or gross anatomical levels known as *disease*. Nevertheless, patients in general and specialty care settings commonly present with physical symptoms and associated disabilities absent explanatory disease in the traditional biomedical sense. "Unexplained" physical symptoms have traditionally been conceptualized as "mental" or "psychological" in nature, and a psychological model of illness causation with its own analogous terminology (psychopathology vs. pathology) and separate system of reimbursement and service delivery (mental health care vs. health care) developed alongside the biomedical model. Despite contemporary understanding that physical and mental health are inextricably linked and that health is a unitary construct, a practical dualism continues to influence our conceptualizations, attitudes, behaviors, and the structure of modern health care.

Illness and disease are associated with cultural expectations. "Sickness" implies individual suffering, lack of responsibility for the illness, and willingness to seek competent medical help (1). The sick are exempted from usual duties and obligations (e.g., school attendance) after a physician has evaluated, diagnosed, and legitimized the illness. While illness associated with disease is readily accepted as "legitimate," the very same symptoms and sufferings in the absence of explanatory disease may be stigmatized as somehow "illegitimate" due to individual weakness, duplicity, or sociomoral failure.

The term somatization has been used descriptively to refer to the experience of physical symptoms where standard medical evaluation reveals no disease or biophysical process sufficient to explain the symptoms or their impact, and such symptoms have commonly been referred to as functional somatic symptoms (FSS) (2,3). A variety of related descriptive terms have been applied to medically unexplained symptoms in the past. For example, the term "neurosis" was initially applied to patients with "nervous symptoms" unassociated with explanatory pathology in the brain or nervous system. Other descriptors such as "psychogenic," "nonorganic," and "hysterical" have typically fallen out of favor after acquiring an inappropriately dualistic and pejorative connotation.

FSS and disorders in children and adolescents are of relevance not simply

because they are common. Affected children do suffer and are viewed by parents as being in poorer health than unaffected peers (4,5). Pediatric FSS are associated with considerable functional impairment, most notably school absenteeism and poor school performance (5–10). Pediatric FSS are also well-known risk markers for current and future anxiety and depressive disorders (11–13) and may predict suicide attempts and completion later in life (14). Children and adolescents with FSS use more health services than unaffected peers (4,5,15), and are at risk to fall between the cracks of a polarized health care system that triages care based on whether a problem is considered to be "physical or mental." They are also at risk for unnecessary medical investigations and treatments that not only put the child at risk for iatrogenic (i.e., physician caused) suffering and harm (16), but also may have the unintended consequence of increasing the family's conviction that the child is "sickly" and that serious disease is being overlooked (6). Patients with FSS and their families may feel profoundly misunderstood or even dismissed after hearing that "nothing is physically wrong." Conversely, efforts to explain away the pain simply as a manifestation of a mental disorder can generate confusion and be perceived as an empathic failure.

This chapter builds upon several previous reviews and will address the clinical challenges posed by children and adolescents presenting for evaluation and management of FSS and associated disorders, describe current attempts at diagnostic classification, and outline a practical approach to management (6–8,17).

NOSOLOGY

Efforts to classify the problems suffered by patients with medically unexplained or FSS diverge depending on whether they were initiated from the general medicine perspective, where the approach has been to develop descriptive diagnostic criteria for functional somatic syndromes based on the organ system of interest, or from the mental health perspective, where FSS have been addressed in the existing classification system for mental disorders.

The way clinicians currently conceptualize FSS and disorders has been influenced heavily by the somatoform disorders classification set forth in American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (DSM-IV) in 1994 and the DSM-IV-TR in 2000. Somatoform disorders were introduced to account for physically ill patients who did not suffer from an explanatory general medical condition or disease and where the symptoms did not appear to be deliberately produced by the patient or perceived to be under the patient's voluntary control (18,19). The somatoform disorders included somatization disorder, undifferentiated somatoform disorder, conversion disorder, pain disorder, hypochondriasis, body dysmorphic disorder, and somatoform disorder not otherwise specified. However helpful these versions of the DSM might have been, clinicians

and researchers alike struggled with the somatoform disorder classification, and some argued that the category should be eliminated entirely, based in part on concerns that the category unintentionally reinforced mind–body dualism by requiring clear-cut distinctions between presumably psychological and physiologic causes for symptoms (20).

Distinguishing somatoform disorders from malingering and factitious disorders often proved difficult, as determining whether a symptom intentionally produced is often based on subjective judgment. Critics also pointed out that common somatic symptoms and concerns presented by patients in ambulatory, nonpsychiatric settings did not receive enough attention (21–25). Finally, children and adolescents were largely excluded in the development of diagnostic criteria and studies of diagnostic validity and reliability.

The DSM-5 groups the entities historically known as somatoform disorders into a section entitled "Somatic Symptom and Related Disorders" (26). The primary diagnoses include somatic symptom disorder, illness anxiety disorder, conversion disorder (functional neurologic symptoms disorder), psychological factors affecting other medical conditions, and factitious disorder, including factitious disorder imposed on self and factitious disorder imposed on others. The two diagnoses of other specified somatic symptom and related disorder, and unspecified somatic symptom and related disorder, capture clinical instances that may not totally qualify for the other diagnoses in this DSM-5 category, but the seriousness and degree of impairment are worthy of diagnosis and treatment focus. The work group charged with updating and reorganizing the DSM-IV somatoform diagnostic category strove to improve diagnostic relevance and utility for primary care and general medical settings. Secondly, somatoform disorders were essentially diagnoses of exclusion, made only after structural or cellular pathologies and/or toxic, metabolic, or chemical insults had been ruled out as etiologies for the presenting symptoms. In other words, the medically unexplained symptoms themselves were the largest focus within the diagnostic schemas. The DSM-5 classification attempts to shift diagnostic attention to the presence of positive, or affirmative, signs and symptoms, such as the association of somatic distress and impairment with abnormal or maladaptive thoughts, feelings, actions, and patterns of behavior (26–32).

Somatic symptom disorder is the diagnosis designed to describe many, if not most, instances in which one or more somatic symptoms cause serious distress or significant disruption in daily living. The individual presents with excessive thoughts, feelings, or behaviors related to the somatic symptoms or associated health concerns as manifested by persistent and disproportionate thoughts about the gravity of the symptoms, a high level of anxiety about health or the symptoms, and/or the devotion of excessive amounts of time and energy to the symptoms and health concerns. This maladaptive preoccupation usually is present for longer than 6 months, though the somatic symptoms themselves may vary and do not need to be

present the entire time. Specifiers include mild, moderate, and severe for symptom number and intensity, and persistent if symptoms are severe with marked impairment and last longer than 6 months. A final specifier is “with predominant pain,” which both captures this disabling subtype and brings the DSM-IV-TR pain disorder into the folds of the new DSM-5 somatic symptom disorder (26).

Illness anxiety disorder is new to DSM-5. It is diagnosed in the presence of a significant preoccupation with having or acquiring a serious illness when there are no somatic symptoms or when existing symptoms are only mild in intensity. If a comorbid medical condition is also present or if the patient is at risk for such a condition, the preoccupation with somatic symptoms is extreme or out of proportion to what would reasonably be expected. There is high anxiety about health, the patient is easily upset by health-related matters, and these behaviors cannot be explained satisfactorily as a manifestation of another psychiatric disorder such as delusional disorder, obsessive–compulsive disorder, or others of the somatic symptom and related disorders group of diagnoses. Specifiers include *care-seeking type* for those who demonstrate either excessive health-related behaviors such as professional appointments, tests, and procedures; and *care-avoidant type,* for individuals whose illness anxiety leads them to complete avoidance of medical professionals and settings. A 6-month period of symptoms is required for diagnosis, though the feared illnesses may change over time. Individuals previously diagnosed with hypochondriasis in DSM-IV-TR will qualify for either somatic symptom disorder or illness anxiety disorder in DSM-5 (26,33–35).

Conversion disorder is an important consideration in child and adolescent medical and psychiatric care. DSM-5 criteria include one or more symptoms of altered sensory or voluntary motor functioning with clinical findings inconsistent or not compatible with known or recognized medical and neurologic conditions. The symptom(s) cannot be explained better by other medical or psychiatric disorders, and cause distress or impairment in social, occupational, or other important domains of functioning and/or require medical evaluation. DSM-5 recognizes the multiple ways symptoms may be expressed, and incorporates ICD-10-CM codes to signify symptom subtypes. Subtypes noted include with weakness or paralysis, abnormal movement, swallowing symptoms, attacks or seizures, anesthesia or sensory loss, special sensory symptom, and mixed symptoms. Other specifiers include acute or persistent episode, and with or without psychological stressors (26,36).

The diagnosis of *psychological factors affecting other medical conditions* is often used by psychiatrists and other clinicians caring for children and adolescents in whom a medical symptom or condition is indisputably present. Psychological or behavioral elements may affect the medical condition adversely by influencing the onset, course, or recovery from the medical condition, or interfere with the proper treatment of the condition. These factors may influence the underlying pathophysiology of the condition, thus affecting the timing of and severity of

symptoms and the need for medical attention or care. These factors present a demonstrable health risk for the individual, and cannot be better explained by the presence of another psychiatric disorder. Specifiers include mild, moderate, severe, and extreme. There is no time length or duration of symptoms specified for this diagnosis, which may also take into account the common scenario of poor or absent treatment adherence (26).

The DSM-5 *factitious disorder* includes two subtypes, *factitious disorder imposed on self* and *factitious disorder imposed on another.* The latter replaces DSM-IV-TR factitious disorder by proxy, commonly known as Munchausen syndrome by proxy. In both types, whether the symptoms are falsified by the patient or others, physical or psychological signs or symptoms are created and there is deception regarding the origin of those signs and symptoms. There are no obvious external rewards for the deceptive behaviors, and the presentation cannot be explained better or more appropriately by another mental disorder. Specifiers denote whether the occurrence is a single episode or recurrent (26).

Other specified somatic symptom and related disorder permits diagnosis of presentations that may fall short of meeting full criteria for another disorder in this category but are nevertheless clinically significant. Examples include pseudocyesis, or the false belief one is pregnant, accompanied by signs and reported symptoms of pregnancy, and brief somatic symptom and illness anxiety disorders of durations less than 6 months (26).

Current discussion and literature both support and applaud the nosologic changes to somatoform disorders in DSM-5, as well as point out shortcomings and areas for future clarification and updates (25,27–37). Minimal literature exists at this time regarding the utility of the DSM-5 diagnostic classifications in the child and adolescent population (38). Therefore, the discussions of epidemiology, assessment, and management that follow remain just as important, if not more so, for contemporary clinical practice.

EPIDEMIOLOGY

Prevalence

FSS and complaints are exceptionally common in children and adolescents, yet most available studies are not comprehensive, relying on self- or parent-report checklists, focusing on some physical symptoms but not others, and failing to include independent medical assessments to determine if the reported symptoms are truly “medically unexplained” (6–9). With rare exception (39), most available studies have focused on the prevalence of specific somatic symptoms rather than the prevalence of specific mental disorders, and standardized research interviews have not typically assessed for the presence of somatoform or somatic symptom disorders

as currently categorized in the DSM-5 (26). With these caveats aside, all manner of FSS have been reported by children and adolescents in clinical- and community-based studies, with approximately half of preschool and school-age children reporting at least one somatic complaint in the previous 2 weeks, and approximately 15% endorsing four or more symptoms (10,40,41).

Although individuals typically focus on a single symptom when presenting for medical evaluation, it has been consistently shown that the presence of one FSS predicts another (42). Children and adolescents with one type of somatic complaint are at significantly greater risk of experiencing other types of FSS, both cross-sectionally and longitudinally (12). Empirical support for a "somatic complaints syndrome" is provided by principal components analysis of parent ratings for over 8,000 youth referred for mental health services (43). Recurrent somatic symptoms were reported by 11% of girls and 4% of boys ages 12 to 16 years in the Ontario Child Health Study (44), and other studies report multiple and frequent somatic complaints in 10% to 15% of adolescents (45). Population-based studies have also found that reports of somatic symptoms tend to cluster, with examples of common symptom clusters including pain/weakness, gastrointestinal (GI), conversion/pseudoneurologic, and cardiovascular (41).

Pain is defined as an unpleasant sensory and emotional experience that is associated with tissue damage or perceived as representative of such damage (46). Although typically considered to signal tissue damage, pain and nociception are not identical, which means that pain can be experienced in the absence of nociceptor activity or can be minimal or absent in the presence of great nociceptor activation. Pain is essentially subjective and must be assessed by self-report. Recurrent complaints of pain are particularly common in children and adolescents. Just over one-third of the children and adolescents assessed in the Great Smoky Mountains Study for headaches, stomach aches, and musculoskeletal pain at multiple time points between the ages of 9 and 16 reported at least one somatic complaint that occurred weekly over 3 months prior to the interview assessment (12). Headaches were the most common complaint (24.7%), followed by stomach aches (9.6%) and muscle aches (8.4%). Perquin et al. (47) found a 3-month prevalence of 25% for painful somatic symptoms, with over half of affected children taking medication and over 40% seeking medical help for the pain.

Headache is the most common type of pain reported by school-age children and adolescents, with 10% to 30% endorsing "frequent" headaches, or headaches at least on a weekly basis (10,12,48–51). Headache is cited as the reason for 1% to 2% of pediatric ambulatory visits (52). The classification system currently in use for headaches is descriptive in nature, since most headaches are considered "primary" and not attributable to an underlying physical disease (53). The primary headaches of greatest relevance are migraine and tension-type headache (TTH). Migraine may be diagnosed when a child or adolescent presents with a history of at least five

headache attacks where the headache lasts 1 to 72 hours (4 to 72 hours in adults); the headache has at least two of the following characteristics—unilateral location, pulsating quality, moderate to severe pain intensity, and/or is aggravated by routine physical activity; and the headache is accompanied by nausea and/or vomiting or photophobia and phonophobia. Migraine may be accompanied by aura, defined as focal neurologic features that may precede or accompany the headache such as visual scintillating scotoma, sensory symptoms such as numbness, tingling, or paresthesias, and motor symptoms such as motor weakness or dysphasia. TTH may be episodic or chronic, with the main features being bilateral location, nonpulsatile quality, mild to moderate intensity, and lack of aggravation by routine physical activity. Dizziness is another common symptom reported by up to 15% of children in surveys (41,49) that may at times be related to migraine.

Functional abdominal pain (FAP) is quite common, with a prevalence of 7% to 25% in school-age youth (54,55), and is responsible for 2% to 4% of pediatric visits (52). It is the most common somatic symptom reported by preschool children (40). Most cases of pediatric abdominal pain prove to be representative of FAP, particularly in the absence of clues to unrecognized disease such as involuntary weight loss, bleeding, fever, other systemic symptoms, or laboratory abnormalities (56). GI symptoms such as nausea, vomiting, and bowel-related complaints are also common, often in association with FAP, and are commonly associated with headaches as well, particularly with migraine (57,58). Gastroenterologists have developed symptom-based diagnostic criteria for functional gastrointestinal disorders (FGIDs), with the most recent iteration (Rome IV) creating three broad categories of pediatric FGIDs: functional abdominal pain disorders (FAPD), functional nausea and vomiting disorders, and functional defecation disorders (56). A recent review reported the worldwide-pooled prevalence of FAPD to be 13.5% (54). Irritable bowel syndrome (IBS) is diagnosed when FAP is related to defecation and/or changes in the frequency or character of bowel movements, and is the most commonly reported FAPD in the pediatric population with an estimated prevalence of 8.8%. Notable among the functional nausea and vomiting disorders is cyclical vomiting syndrome (CVS). CVS has a community prevalence of 1% or less, and is characterized by recurrent and stereotyped episodes of intense, unexplained nausea and paroxysmal vomiting (56). CVS has been associated with migraine (59).

Chest pain is reported by approximately 10% of school-age children and adolescents (6,41), and is a frequent presentation in pediatric emergency rooms and in pediatric cardiology (60,61). Other common pains include musculoskeletal pains such as limb pain and back pain (6,12). Approximately one-third of Finnish youth reported musculoskeletal pain at least once per week in a community study, with 7.5% endorsing widespread musculoskeletal pains in a number of sites and approximately 1% meeting criteria for fibromyalgia (62). Fibromyalgia is characterized by at least 3 months of multiple musculoskeletal aches and pains, most

often in association with fatigue, sleep difficulties, anxiety and depressive symptoms, and pain to palpation on physical examination in so-called “tender points” (63). Other varieties of musculoskeletal complaints may present in pediatric settings, including complex regional pain syndrome type I, or reflex sympathetic dystrophy, which typically develops after immobilization or injury to the limb (64). Clinical features include pain disproportionate to any inciting event such as allodynia (i.e., pain from innocuous tactile stimulation) and/or hyperalgesia (i.e., an exaggerated response to painful stimulation), as well as swelling, changes in skin blood flow, changes in skin temperature, and limitation of functioning. Fatigue is among the most common physical symptoms reported by youth, with up to one-half of adolescents complaining of at least weekly fatigue and 15% reporting daily fatigue (45,65). Chronic fatigue syndrome (CFS), sometimes referred to as myalgic encephalitis (ME) in the United Kingdom, more specifically refers to a condition characterized by severe, disabling fatigue of at least 6 months’ duration where alternative medical and psychiatric explanations (e.g., hypothyroidism, malignancy, hepatitis, narcolepsy, obstructive sleep apnea, medication side effects, major mood disorder, schizophrenia, or eating disorder) have been excluded (66). The Centers for Disease Control and Prevention (CDC) definition requires four additional symptoms from a list that includes sleep disturbance, cognitive difficulties such as self-reported limitations in concentration and short-term memory, postexertional malaise, headaches, and musculoskeletal aches and pains. Prevalence of CFS in adolescents is estimated to be between 0.5% and 2%, and the condition is less common in younger children (66). Using data from the Avon Longitudinal Study of Parents and Children, chronic disabling fatigue of at least 6 months’ duration was identified in 1.3% of 13 year olds and 1.86% of 16 year olds (67). Onset typically follows an acute febrile illness in approximately two-thirds of cases, with Epstein–Barr virus (EBV) being the best known virus associated with CFS (66).

A variety of functional respiratory symptoms have been reported in children and adolescents, including complaints of cough characterized as somatic cough syndrome and tic cough (68), and shortness of breath or dyspnea (69). Vocal cord dysfunction (VCD) is an often unrecognized condition in which presumed vocal cord spasm leads to symptoms that can mimic acute asthma (70). Affected youth may present with a history of “asthma” unresponsive to aggressive medical management. VCD may be differentiated from asthma by the absence of nocturnal symptoms, localization of wheezing to the upper chest and throat, normal blood gases despite extreme symptoms, and significant adduction of the vocal cords when visualized on laryngoscopy.

Conversion symptoms are symptoms that suggest a neurologic illness in the absence of explanatory neurologic disease. Although these symptoms have generated considerable interest in the psychiatric literature, epidemiologic data are relatively sparse and conversion symptoms appear to be unusual in community samples of

Western youth (6,71–74). An Australian population-based study reported an incidence of 2.3 to 4.2 per 100,000 children under 16 years (72) and a more recent UK study found an incidence of 1.3 per 100,000 children between the ages of 7 and 15 (71). Motor abnormalities are the most common presentation at the population level. Presentations with conversion symptoms become increasingly common in tertiary referral centers and pediatric neurology services, where nonepileptic seizures, unresponsiveness, faints, falls, and abnormalities of gait or sensation are the most commonly reported symptoms (75–80). Nonepileptic seizures, in the past sometimes described as "pseudoseizures," resemble epileptic seizures but are not associated with the electroencephalographic abnormalities or clinical course characteristic of true epilepsy, though affected individuals may also suffer from concomitant epilepsy. Relatively little definitive is known about course, though the outcome is favorable in the majority of cases (81), with most resolving within 3 months of diagnosis (82). Though past clinical teaching has emphasized that symptoms considered to be representative of conversion disorder are commonly found to be caused by unrecognized physical disease (83), a systematic review found that the rate of misdiagnosis of conversion symptoms averaged 4% across studies since 1970 (84).

Although hypochondriacal fears and beliefs have not been well studied in childhood and adolescence and the diagnosis of hypochondriasis is quite unusual in younger populations (39), clinical experience and some epidemiologic data suggest that health-related anxiety and fear of suffering from a serious physical disease can be experienced prior to adulthood (15,85). Such illness fears or disease convictions may be rooted in misinterpretation or exaggeration of the threat associated with one or multiple physical sensations, a process sometimes referred to as somatosensory amplification (86). Just over 15% of a sample of Italian adolescents screened positive on a screen for hypochondriacal symptoms and preoccupations (85), and health anxiety has been noted in preadolescents as well, with hypochondriacal fears being associated with FSS, emotional disorders, and increased health expenditures (15). Perhaps counterintuitively, higher levels of illness fears were associated with less health behaviors such as smoking, illicit substance use, poor sleep habits, and physical inactivity. Health anxiety has also been noted in younger children (15).

A prospective epidemiologic study that applied past diagnostic criteria for somatoform disorders in a sample of 3,021 German youth aged 14 to 24 years found the lifetime prevalence of any specific somatoform disorder to be 3% at baseline, and clinically meaningful somatoform illness that did not meet diagnostic criteria for a specific somatoform disorder was reported by an additional 10% of the sample (39). Complaints of pain were most common, but no specific cases of somatization disorder or hypochondriasis were identified in children and adolescents, and the lifetime prevalence of conversion disorder was 0.3%.

Individual and Sociocultural Factors

Reporting of FSS appears to increase with increasing age into adolescence (6,50). Although headache is the most common complaint of pain across childhood and adolescence, FAP is likely the most common complaint in early childhood, with headache prevalence peaking at approximately age 12 (40,50). Polysymptomatic presentations become more common in adolescence (44,87,88). Conversion disorder is especially rare in very young children, and clinicians should be skeptical of presumed conversion symptoms in children younger than age 6 years (6,75,76,89).

In general, FSS such as recurrent complaints of pain occur equally in boys and girls until late childhood and puberty, after which female symptom reporting predominates (6,8). Chronic fatigue (66) and hypochondriacal fears (85) are more common in females, and conversion symptoms are more common among girls than boys across all age groups (77–79). Girls tend to use health services for FSS more than boys (47) and are more consistent in symptom reporting across time (6). Female gender predicts the persistence of FSS and related disorders in adolescents, along with depression and poor self-rated health (39,90).

Low socioeconomic status and lower levels of parental education have been associated with somatic symptom reporting in childhood and adolescence in some studies (4,39,91), as well as with symptom stability (39), but not in others (88). Though often considered a disorder of the upper strata, CFS appears to be more common in children exposed to social deprivation (66). The impact of race/ethnicity and the role of social and cultural factors have been inadequately studied, but culture does appear to be influential. For example, conversion symptoms are reported to be common presentations of psychiatric disorder in non-Western clinical settings, including Turkey and India, and cultural differences in pain expression and behavior have been suggested (6). Unfortunately, existing studies may confound ethnicity, socioeconomic status, and acculturation.

Lack of exercise, sedentary behavior, and low levels of physical fitness have been associated with a variety of FSS in children and adolescents (90) and specifically with CFS (92).

Psychopathology and Temperament

FSS are consistently associated with anxiety and depressive symptoms and disorders in children and adolescents both cross-sectionally and longitudinally, and the likelihood of concurrent anxiety or depression increases with the number of FSS reported (11). Children and adolescents with FSS in the methodologically strong Great Smoky Mountains Study experienced higher rates of anxiety, depression, and behavioral disorders than peers, and were significantly more likely in adulthood to suffer from depression, generalized anxiety, and “combined distress disorders” of

mixed depression and anxiety, suggesting a specific relationship between pediatric FSS and later depression and generalized anxiety (12). Persistent FSS across developmental periods were particularly strong predictors of later emotional disorders, and FSS in childhood also predicted suicidality in later life in bivariate analysis, but the finding attenuated in multivariate regression. In a large Finnish sample, FSS at age 8 predicted antidepressant use in young adulthood, and childhood abdominal pain predicted later suicide attempts and completions in boys, but not in girls (14,93).

High rates of psychiatric symptoms and disorders have been consistently observed in studies comparing children and adolescents with FSS to unaffected controls, with particularly high rates of anxiety and/or depressive symptoms and disorders reported in association with FAP, headache, musculoskeletal pain, and chest pain (8,11,12,94). An anxiety disorder can be diagnosed in approximately three-quarters of youth with FAP presenting in primary care (95) and specialty care (96,97). Youth suffering from CFS also report higher levels of anxiety and depressive symptoms and disorders than healthy controls (66,92). Comorbid emotional disorder likely contributes to the functional impairment experienced by youth with FSS (98).

Just as internalizing psychiatric symptoms and disorders appear to be overrepresented in children and adolescents with FSS and disorders, children with internalizing disorders are more likely to suffer from FSS such as FAP and headache (99). A systematic review of the relationship between FSS, anxiety, and depression concluded that childhood anxiety and depression predicted FSS later in life (11), and depressive symptoms appear to be a predictor of the persistence of FSS (90). A longitudinal study of somatoform disorders in adolescents and young adults found pre-existing anxiety, depressive, and substance use disorders to be associated with the new onset of somatoform disorders, and also reported that depression and substance abuse were associated with persistence of FSS (39). Children with autism spectrum disorder also appear to suffer higher rates of functional GI symptoms such as abdominal pain and bowel complaints than controls (100).

Temperamental traits such as behavioral inhibition, harm avoidance, neuroticism, and negative affect have been consistently associated with FSS, anxiety, and depression (95,101), and trait neuroticism prospectively predicts headaches and stomach aches in adolescents (102). These traits share associations with pessimistic worry, fear of uncertainty, and a tendency to respond to environmental challenge at lower thresholds (103,104). Children and adolescents with conversion disorder showed significantly faster reaction times to sad faces than did healthy controls in a study that examined reaction times to facial expressions of emotion, suggesting greater vigilance to expressions of negative emotion and interpersonal threat (105). Physiologic responses of youth with FAP to a social stressor also appear more akin to those of anxiety-disordered youth than of healthy controls (106). Anxiety sensitivity, a tendency to fear bodily sensations associated with anxious arousal

based on the belief that they signal real harm, has also been associated with FSS.

Taken together, it is plausible that youth with FSS, anxiety, and depression may share a common tendency to respond to perceived threat with some combination of somatic and cognitive emotional distress (11). It has also been suggested that children with FSS may be "hypersensitive" to pain or "pain prone," responding to painful stimuli at lower thresholds that controls (107). Given existing evidence for a shared neural system that mediates both physical discomfort and social distress, it is plausible that individuals at risk for FSS may indeed be more vulnerable to the impact of both physical pain and social adversity (108).

Life Events and Trauma

A variety of negative experiences and stressors have been associated with FSS in childhood and adolescence, including maltreatment (6,8). A recent study found that the combined severity of negative life events predicted FSS in adolescents even when adjusted for pre-event levels of FSS and anxiety and depression (109). Although most children with FSS have not been maltreated, sexual abuse predicts FSS in children and adolescents (39,110,111). Exposure to parental neglect and the experience of poor care in childhood have also been associated with FSS later in life (112,113). Persistence of FSS has also been associated with exposure to traumatic events (39), and youth with posttraumatic stress disorder appear to be at increased risk of FSS and somatoform disorders (114).

Family and Genetic Factors

The experience of FSS can be familial, and youth with FSS are more likely to have parents and family members who experience higher levels of FSS and report negative health perceptions than unaffected peers (6–8,50,80,87,88,115–120). Recurrent pain such as FAP and headache is more likely to be reported by the family members of affected youth than by those of controls, raising questions regarding so-called "pain-prone" families (108). CFS tends to cluster in the families of affected children, and twin studies suggest a heritable component (65,66,92). Children of parents with somatization disorder have also been found to endorse higher levels of FSS than children of controls (116). Anxiety and depressive symptoms and disorders are associated with FSS within families and across generations (11).

Exposure to illness in a parent has been associated with later FSS, and offspring of adults with FSS are more likely to suffer from health anxieties and higher levels of health service use for FSS than those of controls (117). Parents may influence the experience of FSS in children and adolescents via a number of psychological mechanisms, most notably by reinforcement of illness behaviors and social learning through modeling (121). Selective attention to the expression of FSS and limiting the

child's activities and responsibilities can reinforce illness behavior and increase disability associated with the symptoms (118,121). Parents of youth with FSS have been described as overprotective and prone to view their children as particularly vulnerable, which may increase the degree to which the child's symptoms are viewed as threatening. Clinical observers often note that there is a family "model" for an ill child's FSS, suggesting that family members may model maladaptive illness behaviors and methods of coping with FSS, emotional distress, and adversity.

Family systems theorists have sometimes understood pediatric FSS as serving a specific function within the family system, with the child's symptoms potentially allowing the family to avoid conflict, most notably parental–marital conflict, and thus preserving family homeostasis (122,123). Families of youth with FSS are more likely than those of peers to be described as low in perceived support, and affected children are more likely to come from nonintact families and those characterized by parental–marital conflict (5,120). Some observers have also called attention to how a particular child's somatic symptoms may serve a communicative function in the family on the order of "body language" or a "plea for help" (124,125).

Genetic and environmental factors play an interactive role in the development of FSS and related disorders, but some evidence suggests a prominent heritable component (118,126–130). A functional polymorphism in the promoter region of the serotonin transporter gene has been associated with FSS (131,132), as well as trait neuroticism and anxiety (133,134). Other polymorphisms in genes important to the metabolism of specific neurotransmitters have been related to susceptibility for FSS, including association of a polymorphism in catecholamine-*O*-methyltransferase (COMT) with pain sensitivity (135) and in the gene coding for tryptophan hydroxylase, the rate-limiting enzyme in the biosynthesis of serotonin, with somatic anxiety (136), but subsequent studies of potential associations with FSS have been unrevealing (137,138).

Coping

Vulnerability to FSS may be understood as being derivative of individual differences in stress reactivity, stress exposure, threat appraisal, distress tolerance, and coping skills (139,140). Coping refers to voluntary efforts to regulate emotion, thought, behavior, and/or environment in response to challenge or adversity. Several coping styles have been described, and some appear to be more adaptive than others with regard to the management of FSS and emotional distress. Active coping applies problem-focused strategies to resolve the FSS and make the discomfort "go away." In addition to problem solving, active coping strategies may sometimes include emotional expression and emotional regulation. Accommodative coping is characterized by efforts to accept and adjust to adversity, generally by regulating attention or thought patterns via strategies such as acceptance, distraction/ignoring,

self-encouragement, and cognitive restructuring. Accommodative strategies are consistently associated with lower levels of FSS and emotional distress in youth. Passive coping reflects strategies that avoid confronting pain such as avoidance, denial, and wishful thinking, and is considered maladaptive given strong associations with worsening levels of pain and emotional distress in children (141,142). Existing research highlights the importance of exaggerated threat appraisal in magnifying and sustaining FSS, and how beliefs about the nature of the illness may influence choice of coping strategy (65,143). Unchecked fears that the child's illness represents a serious threat to the child and family can provoke maladaptive responses that may be active, such as frenetic efforts to "make it just go away," or passive, such as despair and a wish to "give up," rather than more adaptive accommodative responses (143).

Persistence

Somatic symptom reporting early in life predicts FSS later in life. Predictors of persistent FSS include female gender, poor self-rated health, and depression (144). Children who complain of stomach aches at the age of 4 are three times more likely to have similar complaints on follow-up at age 10 than peers (145). Early follow-up studies reported persistence of FAP into adulthood for one-third to one-half of affected children (16,146–148). Young adults with a childhood history of FAP not only are more likely to report more FSS than controls with no history of childhood pain, but are also much more likely to experience psychiatric symptoms and disorders in adulthood, particularly anxiety and depressive disorders (12,13,119,149). Adults with multiple FSS are more likely to have experienced physical illness before age 17 than other ill adults (112).

ASSESSMENT AND DIAGNOSIS

Approach to the Patient and Family

Assessment establishes the foundation for successful intervention, and both content and process are critically important (17). Empathic acknowledgment of the patient's suffering and the family's very real fears and concerns can aid in establishing a working partnership, and it is both unproductive and presumptuous to challenge the subjective reality of the child's symptoms. Clinicians managing patients with FSS do well to remember that empathic failure by professionals can generate embarrassment, anger, and even a perceived sense of entitlement on the part of patients and family members. Patients and especially parents may fear that the child's symptoms indicate the presence of a life-threatening disease, yet may also be concerned that the child's presentation might be perceived as feigned, imaginary, or an indication of personal weakness or family dysfunction. Youth presenting with FSS have often visited a

variety of health care professionals prior to referral for consultation with a psychiatrist or other mental health professional, making it important to explore patient and family experiences with previous providers. For example, families may have had experiences that generated mistrust of medical professionals and the health care system in general, and it is not uncommon for patients and families to believe that the child's FSS have not been taken seriously or have been "dismissed" by previous providers. Patients and families may bristle if they believe they are being told that "nothing is wrong" after weeks or months of worrisome physical symptoms and distress—not to mention several hours in a waiting room.

Patients and families may misinterpret psychiatric referral as an indication that the child's symptoms have not and will not be taken seriously. Conversely, mental health professionals risk a loss of credibility if the child's physical suffering is approached narrowly as being purely "psychological" or as a consequence of "stress," without exploring other possible explanations and the beliefs of the patient and family. Concerns related to stigma can interfere with the willingness of patients and families to engage with mental health professionals and even motivate patients, families, and clinicians to push for potentially dangerous and unnecessary medical investigations and procedures. Ideally, psychiatric assessment will take place within the context of a relationship with a collaborating primary care physician or specialist.

Multiple sources of information are helpful, with important resources beyond the patient including parents, other professionals, teachers, and school nurses. Useful questionnaires with child and parent self-report versions include the Children's Somatization Inventory (CSI), a measure of the presence and intensity of a variety of somatic symptoms (150) and the Functional Disability Inventory (FDI), an assessment of impairment associated with FSS (151). It is important to explore a particular symptom's timing, context, and characteristics, as well as to examine associated social reinforcements and other potential benefits associated with the child assuming the sick role. Parents may inadvertently encourage sick role behaviors by responding to complaints of pain with attention, rewards, or opportunities to avoid unpleasant activities or school (121,152). Identifying any school difficulties can be especially relevant, since learning problems or peer problems such as bullying can reinforce absenteeism. The child's FSS may become part of a self-handicapping strategy by becoming a ready "explanation" for the child not performing up to expectations (152).

Differential Diagnosis

The specific components necessary to a competent assessment of the youthful patient with presumably "medically unexplained" physical symptoms are best determined on a case-by-case basis and dictated by clinical judgment and experience, but should be informed by the development of a differential diagnosis at the outset. Thoughtful

clinicians will remain alert to the possibility of unrecognized physical disease, conduct the assessment with an open mind, and communicate an unwillingness to prejudge the etiology of the symptom. Previous records should be carefully reviewed, and there should be no reluctance to initiate additional medical evaluation if the assessment generates new concerns about physical disease or if the clinical picture appears to be changing over time. A balanced approach that avoids excessive testing is nevertheless of great importance, since unnecessary medical tests and treatments carry the risk of iatrogenic disease, as well as of miscommunicating physician uncertainty, which can help maintain or worsen FSS and related disorders (8,17).

There is no simple answer to the question as to when the medical workup is complete, since it may be impossible definitively to rule out unrecognized disease, but unless the treating professionals are reasonably comfortable that serious physical disease has not been missed and are able to communicate this conviction to the patient and family, it is difficult to adequately build a solid foundation for intervention. A given symptom may prove functional despite the presence of a coexisting physical disease, as the simple presence of disease (e.g., epilepsy) does not exclude the possibility of a functional disorder (nonepileptic seizure) and FSS are commonly observed to develop following an acute physical illness or accident (6–8). Beyond unrecognized physical disease, medically unexplained symptoms in a child or adolescent most often are considered functional or FSS, meaning that they are quite real and subjectively outside the patient's sense of voluntary control. From the mental disorder perspective, FSS and syndromes are generally classified as being representative of a somatic symptom disorder or understood as a component of an anxiety or depressive disorder. In addition, "psychological factors affecting medical condition" may be the diagnosis if the FSS is codified by the diagnostician as a general medical condition where emotional or psychological factors are impacting on the illness. As noted previously, the many decision points requiring a clinician to judge "physical versus mental" certainly complicate the diagnostic process and can affect diagnostic reliability. So-called positive findings or clues to a symptom being considered functional go beyond simply eliminating or ruling out physical disease. Such clues include contiguity of the symptom with a psychosocial stressor or stressors; the presence of another diagnosable psychiatric disorder; the association of a symptom with some interpersonal, familial, or social gain for the patient (secondary gain), or even a presumed intrapsychic gain (primary gain); existence of a model for the symptom within the child's immediate environment; a communicative or symbolic meaning for the symptom within the family or immediate social milieu; the violation of known anatomic or physiologic patterns by the symptom; and the response of the symptom to placebo, suggestion, or psychological treatment. Clearly, these clues should not be considered to be definitive in any way, since virtually all could be found in association with physical disease (e.g., asthmatic

bronchoconstriction that responds to placebo or suggestion). However, a constellation of such clues taken together is most persuasive (6–8,17). For example, while “*la belle indifférence*” (an apparent lack of concern in relation to the symptom) has often been considered to be suggestive of conversion disorder, it hardly constitutes proof that a given symptom is functional (153).

In circumstances where the child’s physical symptoms are judged to be intentionally produced or feigned, FSS and disorders are distinguished from factitious disorders and malingering (26). In factitious disorder, physical symptoms are deliberately feigned or self-inflicted by the patient, with the patient’s goal appearing to be an internal one in the form of the psychological gain presumably associated with the sick role. In factitious disorder by proxy, a parent or caretaker feigns, simulates, or causes disease in a child with the motivation being an internal one for the caretaker. Malingering is the deliberate feigning, simulation, or production of physical symptoms in pursuit of an external incentive, such as the avoidance of a particular responsibility or punishment, or the pursuit of financial gain. Inconsistencies or apparent fabrications in the history should raise concerns about these uncommon but real problems. Medical or psychiatric records hand-carried by a parent are certainly not uncommon, yet should provoke at least mild suspicion given that record tampering has been reported in some cases of factitious disorder by proxy.

Careful assessment of the social and family environment is similarly critical. Family history of psychiatric disorder, functional somatic syndromes, chronic physical illness, and disability should be explored, with attention to known risk factors. Because pediatric FSS are commonly associated with separation fears, consideration should be given to experiences which may have led to the family perceiving the child to be especially vulnerable from a physical or emotional perspective (154). Other relevant areas include possible marital conflict and parent–child relational problems, as well as other negative life events. Perhaps the most critical environmental issue to consider is that of maltreatment, which is particularly relevant in youth suffering from conversion symptoms, genitourinary complaints, and chronic polysymptomatic somatization.

Diagnosis and Psychoeducation

The diagnostic impression should be developed carefully, often in consultation with the referring provider, and discussed in the context of a collaborative relationship with the patient and the family. It is generally wise for the clinician first to review and gather consensus with regard to the number and types of physical, emotional, and behavioral symptoms noted during the assessment, as well as the time course and context of the symptoms with the patient and family prior to arriving at and discussing the diagnosis formulation. In circumstances where there is confidence in the

diagnostic formulation, the diagnosis should be discussed clearly, frankly, and directly with the patient and family together (8,17). Once a diagnosis has been made with reasonable confidence, additional medical workup should be avoided in the absence of new information, a change in clinical status, or a strong conviction that a relatively low-risk investigation is needed to reassure the patient and family in order for treatment to proceed. When the diagnosis is presumptive or uncertain, truthful acknowledgment of uncertainty is superior to feigned certainty or avoidance. Humility is essential since presumably "medically unexplained" symptoms are sometimes just that—truly unexplained. Said differently, there may be occasions where the consensus of evidence suggests that a particular physical symptom is best considered simply unexplained in the usual sense.

Competent education of the patient and family provides a solid foundation for treatment, challenges stigma, and instills hope and positive expectations. The clinician should avoid communicating any sense of unease or embarrassment about the diagnosis, since this might contribute to treatment resistance and a wish to perpetuate the search for unrecognized disease. Patients and families can be educated about how physical symptoms of distress in the absence of serious disease are common and considered to be quite real by physicians and other health care professionals, and should be reassured that although our knowledge base is limited, much practical help is still available. Examples of common psychophysiologic reactions, such as cold or sweating hands associated with nervousness or heart racing in response to excitement, may be useful. Discussing the relationship between mind and body and the false dichotomy implied by separate systems of care for "physical" and "mental" disorders can also be useful. Efforts to explain FSS purely as reactions to adversity or stress may sometimes prove unproductive, since the patient may not recognize the presence of stress, may believe that illness in response to stress implies personal weakness, or may jump to the potentially maladaptive conclusion that avoidance of all life stress is the solution.

Education about the nature of painful FSS may be helpful to patients and families. Pain is typically perceived as a signal of threat to organismal integrity and accompanied by a wish to avoid additional discomfort and physical harm. Patients with FSS may benefit from knowing that some individuals may be especially vulnerable to experiencing bodily sensations as painful and a special threat to health. For example, youth with FAP may be especially sensitive to gut sensations or discomfort (155,156). Like fear, pain can serve a defensive neurobehavioral function, steering the organism away from perceived threats and motivating adaptive behaviors. Functional pain is essentially pain in the absence of demonstrable tissue damage, and is analogous to psychopathologic anxiety, which may be understood as fear inappropriate to context. The pain sensitivity observed in youth with FAP creates conditions for abdominal pain inappropriate to context (i.e., pain in the absence of tissue damage). The analogy of an overly sensitive car alarm that is

triggered by simply walking past the car rather than a real attempt to enter or damage the vehicle can sometimes be helpful in educating patients and families about the sort of vulnerability to experience bodily sensations as painful and threatening often exhibited by youth with FSS.

The collaborative nature of the treatment process should be discussed early and often, and the importance of a therapeutic partnership—the foundation for therapeutic success emphasized. Patient, family, and professional roles and responsibilities should be delineated, with an emphasis on solid communication and the importance of working together. Determining shared functional goals for the patient, family, and treating professionals is an important task, as it deemphasizes unequivocal "cure" and encourages the rehabilitative mindset that typically serves as the successful foundation for treatment.

MANAGEMENT

Children and adolescents presenting with one type of FSS commonly experience other FSS, and FSS and disorders are often comorbid with anxiety and depressive symptoms and disorders, suggesting a common pathophysiology (11). The management model presented below builds upon common approaches and a few core principles distilled from the available pediatric and adult treatment literature. It should nevertheless be understood that successful interventions for one type of FSS or disorder may not prove effective for other FSS and disorders and that well-designed trials of specific interventions are a requirement of evidence-based medicine.

Therapeutic approaches to FSS and disorders often share common features, but care for individual patients is best individualized (17,157). Randomized controlled trials of interventions for youth with FSS are relatively sparse, so much of what follows is a synthesis of available evidence and accepted practice. Child and adolescent psychiatrists and other behavioral health professionals may be helpful as formal or informal consultants to primary care physicians and general medicine specialists, who are most often "out front" in managing children with FSS, but youth with FSS and their families may resist psychiatric referral, either actively or passively. Communication and coordination between the consultant and the referring physician are critical in maintaining the referring physician–patient alliance and avoiding unnecessary "doctor shopping."

Reassurance

Reassurance that a life-threatening or serious physical disease is not present is often a necessary step in the treatment process. It is usually essential for the patient and family to view the presenting symptoms as less threatening, as it is often difficult to

proceed with intervention until fears related to the FSS have decreased. Parents must understand that the child's quite real subjective distress does not appear to be associated with actual tissue damage. If it is suspected that the parents fear that a serious diagnosis such as cancer has been missed, the feared diagnosis and the rationale for eliminating it from serious consideration should be specifically discussed. Excessive reassurance may nevertheless prove counterproductive in cases where obsessional illness worry and hypochondriacal fears are prominent. In such cases, the illness worry should be addressed directly and framed as a problem to be solved rather than attempting to overcome it by reassurance alone.

Rehabilitative Approach

Many authors have discussed the advantages of a rehabilitative approach to pediatric FSS (8,17,157). By encouraging the patient to return to usual activities and responsibilities prior to definitive symptomatic relief and by discouraging illness-related behaviors, the rehabilitative approach directs the patient and family focus away from finding a "cure" to instead finding a way to cope with and overcome a distressing physical problem. This approach challenges the notion that symptom resolution is necessary for the child to return to normal functioning, and can empower the patient and family by shifting the burden of responsibility for therapeutic success to the patient in the context of professional support and encouragement. The metacommunication of a rehabilitative approach is that the child will not be harmed by activity and effort, which can help neutralize concerns about FSS and foster health-promoting behaviors for both child and parents. Achievement of functional goals is understood and acknowledged as a personal success due to individual courage and hard work, and rightly treated as an accomplishment of which the patient can be proud of. The rehabilitative approach has been applied with some success in CFS, producing superior results to energy management strategies such as "pacing" that involve accepting the limitations associated with the illness and resting based on subjective need (158). Indeed, there is little evidence that rest alone is helpful in CFS, and may in fact exacerbate the condition (65). In keeping with a rehabilitative model, the use of physical therapy has sometimes been advocated, including in the management of conversion disorder (159).

Cognitive factors such as expectations and beliefs that the child's symptoms signal the threat of tissue damage appear to be important in youth with FSS, and addressing such concerns has been associated with response to psychotherapy (160). The rehabilitative approach challenges misperceptions about the child's health and capabilities, and serves as the linchpin of a cognitive-behavioral strategy by emphasizing the child's fundamental health, strength, and adaptability. Success largely depends on the clinician's ability to address patient and family anxiety about the child's illness and to successfully challenge patient- and family-distorted health

beliefs. Parents and caretakers must understand that rehabilitative expectations in the face of the child's real distress are not cruel. Instead, a discussion of how kindness demands a firm approach is often indicated. Clinician speech and behavior should communicate that the child is fundamentally strong, competent, and capable of overcoming the challenge presented by the illness. To expect less may actually be countertherapeutic and representative of "misplaced kindness." Specifically, school attendance and performance should be emphasized as critical indicators of developmentally appropriate functioning. Homebound instruction is sometimes sought by youth with somatoform illness and/or their parents, but should almost always be avoided or challenged by treatment professionals. Respect for the importance of school should be communicated by attempting to schedule follow-up visits outside of regular school hours whenever possible.

Psychotherapeutic Interventions

Recent systematic reviews found psychological therapies to be beneficial in reducing pain intensity for children and adolescents with headache and other recurrent pains when delivered face to face (161,162) or remotely via the internet, computer program, audiotape, smartphone, or telephone (163). Cognitive-behavioral therapy (CBT) addresses attitudes, cognitions, and behaviors that may generate or maintain FSS, and has been reported to be helpful, often as part of a multimodal intervention, in the treatment of headache (164), FAP (165–167), fibromyalgia (168), and CFS (158,169). Interpersonal and expressive psychotherapies have not been systematically studied in the treatment of pediatric FSS, but case reports suggest they may be useful, particularly in the presence of psychological trauma (170).

Behavioral and operant interventions are common to most successful interventions, with core features being the reward of health-promoting behaviors and the discouragement of illness behaviors and disability. Most behavioral interventions emphasize positive reinforcement for functional improvement, as well as *extinction* or withdrawal of reinforcement for illness-promoting behaviors (17). The use of punishment per se is not advisable. Negative reinforcement, which produces an increase in the frequency of a desired response by removing an aversive event immediately after the desired response, has typically been applied by lifting restrictions theoretically imposed by illness contingent upon functional improvement (17,171). For example, discharge from the hospital might be allowed only if the patient demonstrates convincing clinical improvement, or persistent bed rest might be imposed with removal contingent on the patient returning to premorbid functioning and responsibilities such as school attendance. Implementing behavioral interventions typically requires a strong therapeutic alliance with the family, as parents may have difficulty cooperating unless their illness-related fears and concerns have been addressed.

Encouraging results have been reported with the use of self-management strategies, including self-monitoring, training in coping and relaxation, guided imagery, hypnotherapy, and biofeedback (162,172). Such strategies not only offer symptomatic relief, but may also encourage more active coping strategies, which may help improve functional status.

Family therapy and family-based interventions have been advocated (122,123) and a family focus has often been included as a component of CBT-based interventions (166,167). Since children with FSS are more likely as a group to be viewed as health impaired and have sick role behaviors inadvertently encouraged by parents, it is important to respectfully challenge the perceived physical vulnerability of the child and any familial encouragement of illness behavior (160,167). Group psychotherapy has not been systematically evaluated in the management of pediatric FSS.

In summary, psychotherapeutic approaches to FSS in children and adolescents seek to help child and family: (1) diminish the perceived threat associated with the FSS; (2) modulate affective and physiologic reactivity to relevant environmental or physical triggers; (3) promote healthy coping by encouraging accommodative coping strategies such as acceptance, distraction, self-encouragement, and cognitive restructuring, while discouraging passive strategies such as avoidance, denial, and wishful thinking; (4) optimize social reinforcement by using positive reinforcement for healthy behaviors and withdrawal of reinforcement for illness behaviors; and (5) strengthen the child's perceived competence and self-worth.

Suggestion and Placebo

Though sometimes tempting, particularly to generalists, the use of placebo and/or sham interventions is discouraged for both ethical and practical reasons. Such efforts may inadvertently contribute to patient and family convictions that the symptom is caused by physical disease, and if suggestion or placebo prove unsuccessful, the clinician is then forced to perpetuate new deceptions or must backtrack and attempt to convince the patient that serious physical disease is absent and that symptom removal is not really necessary for functional improvement to take place.

Psychopharmacologic Treatment

Pharmacologic management has the advantage of relative simplicity and acceptability within general medical settings, and is in keeping with traditional office practice. Unfortunately, large randomized controlled trials of psychoactive medications in the treatment of pediatric FSS and disorders are relatively lacking, so psychopharmacologic treatment of youth with FSS has largely been presumptive and based on experience with adults. Psychopharmacologic interventions are

nevertheless worthy of consideration in the treatment of refractory and/or painful FSS, GI symptoms, or fatigue, particularly in the presence of psychiatric comorbidity or when psychotherapeutic interventions have not been entirely successful. Antidepressant medications have been reported to be of benefit in the treatment of a number of somatoform disorders and FSS in adults, including somatoform pain, IBS, and a variety of other FSS and syndromes such as fibromyalgia, FGIDs, and headache (173). Because pediatric FSS are commonly associated with comorbid internalizing symptoms and disorders (11) attention to comorbid psychopathology is very much indicated and clinical experience suggests that active intervention for comorbid anxiety and depression can ameliorate the functional impact of associated FSS. In the clinical setting, medications such as SSRIs, selective serotonin–norepinephrine reuptake inhibitors (SNRIs) such as duloxetine and venlafaxine, other novel antidepressants such as mirtazapine and milnacipran, benzodiazepines, and antipsychotics have been used anecdotally in pediatric patients struggling with FSS, but randomized controlled trials have been lacking in general. Although medications used for FSS that are not typically considered to be psychoactive are not within the scope of this chapter, they may be worthy of exploration in the care of individual patients.

The literature on the psychopharmacologic treatment of pediatric FAP has been judged to be inconclusive and inadequate (174,175). Although an open trial of citalopram for pediatric FAP reported positive response in 21 of 25 (84%) treated youth (176), subsequent randomized controlled trials have produced mixed results. An Iranian study that randomized 115 school-age children and adolescents to citalopram 20 mg daily or placebo in a 4-week trial failed to demonstrate statistically significant between-group differences on intent-to-treat (ITT) analysis, but completer analysis revealed statistically significant reductions in pain and the clinical global severity for the citalopram group (177). Another as yet unpublished double-blind, placebo-controlled trial that randomized 81 subjects ages 7 to 18 years to citalopram or placebo for 8 weeks failed to demonstrate the superiority of citalopram versus placebo on ITT analysis of clinical global improvement and abdominal pain using a mixed effects model, but citalopram was superior in reducing global illness burden relative to placebo ($p = 0.037$). Endpoint analysis for the ITT sample revealed a trend favoring citalopram with 52.5% of citalopram-treated subjects rated “much” or “very much” improved relative to 31.7% of placebo-treated subjects ($p = 0.058$), but no between-group differences in reported abdominal pain. Endpoint analysis for completers classified 60.0% of citalopram-treated subjects as responders compared to 29.7% of those taking placebo ($p = 0.010$). Citalopram was well tolerated relative to placebo in both controlled studies, and there were no serious adverse events (178).

Though pediatric gastroenterologists have often favored the use of tricyclic antidepressants in youth with FAP based in part on adult experience, controlled trials

have failed to demonstrate efficacy (174,175,179). It is thus difficult to advocate their use, particularly given the potential for toxicity in households with young children, past reports of sudden death, and the lack of proven efficacy in pediatric emotional disorders.

With regard to pediatric headache, both acetaminophen and ibuprofen have been shown to be effective in the acute treatment of pediatric migraine, as has sumatriptan nasal spray (180). Antipsychotic medications such as chlorpromazine, prochlorperazine, and haloperidol have been used effectively in the acute management of adult migraine with effects comparable to sumatriptan, though pediatric experience is limited (181). Antidepressant medications such as amitriptyline and trazodone, anticonvulsants such as topiramate, beta-adrenergic blockers such as propranol, and cyproheptadine have been applied to the management of pediatric headache, but data remain insufficient to draw firm conclusions about efficacy (162,182,183). The alpha-adrenergic agonist clonidine has not demonstrated efficacy and is most likely ineffective. Serotonergic antimigraine drugs such as sumatriptan have been used in combination with serotonergic antidepressants (184), but caution is suggested given the U.S. Food and Drug Administration (FDA) warning about the risk of serotonin syndrome issued in 2006 and the relative paucity of research (185).

The use of low-dose clonidine in adolescent CFS had a negative effect on physical activity relative to placebo, and was not clinically useful despite reductions in markers of sympathetic outflow and inflammation (186). Given the common association of anxiety and depressive disorders with the symptom profile in CFS, consideration might be given to the use of antidepressant medications, including more activating antidepressants such as bupropion, though such approaches cannot be recommended as standard practice and deserve careful study.

Clinical experience suggests that some patients who experience physical symptoms associated with emotional arousal and anxiety may benefit from a short course of a benzodiazepine such as clonazepam or lorazepam, which can sometimes produce rapid symptomatic relief, help reassure the patient and family, and demonstrate the potential contribution of emotional activation to somatic distress (8,17). For youth with refractory symptoms of nausea or vomiting in the presence of symptoms suggesting acute migraine, the brief use of an antipsychotic medication or antiemetic such as ondansetron may be worthy of consideration.

Coordination of Care

Successful communication and collaboration with other professionals involved in the child's care, including teachers and school nurses, can prove critical to success over time. Because FSS commonly present in general medical settings, a close working relationship with the primary care physician or referring specialist is essential. As

integrated care models of health care delivery become more widespread, effective communication between medical and mental health providers becomes easier. Poor communication is the most frequent complaint made by pediatricians about child and adolescent psychiatrists (187), and increases the risk that treatment efforts will be misapplied, diluted, or overlooked. A simple consultation letter outlining a general approach to adult somatization disorder patients from a consulting psychiatrist to primary care physicians was shown to be effective in improving patient satisfaction and reducing disability and health care expenditures (188). Because absenteeism from school is common in youth with FSS, communication and collaboration with school officials can prove instrumental in developing a rehabilitative plan. The clinician can serve as a bridge to help bring together the school and the patient's family. A retrospective excuse for past school absences can be negotiated with the family and school as being contingent upon the child's commitment to a forward-looking management plan which will treat subsequent absenteeism for known FSS as inexcusable. It is thus useful to define what constitutes a legitimate, medically excused absence for the child, family, and school, and the physician who will be responsible for legitimizing medical excuses should be specified beforehand in order to prevent doctor shopping in search of medical excuses. Absence from school without the approval of the treatment team can then be legitimately viewed as truancy, allowing the school to leverage attendance and benefit overall treatment efforts.

Ideally, coordination of the child's medical care should be consolidated with a single physician or clinician. Regularly scheduled medical visits can prove useful in reassuring the patient and family that their concerns have not been dismissed (188). The primary physician may serve as a powerful attachment figure for patients and families. Regularly scheduled visits allow the patient and family to see the physician without the requirement that the child be sick.

CONCLUSION

The study and management of pediatric FSS and associated disorders remain handicapped by problems of conceptualization and classification. Clinicians often feel confused and intimidated by these patients, their distressed and sometimes demanding families, and the general medical colleagues who call on us for help. New ways of conceptualizing and managing the problems posed by patients with swill require additional epidemiologic, mechanistic, and treatment studies. Future studies should examine not only the efficacy of tested interventions, but whether symptomatic and functional improvements are independent of changes in comorbid anxiety and depressive symptoms. The need to develop relatively potent, tiered interventions applicable to primary care and other general medical settings is clear given the prevalence and impact of FSS in children and adolescents across the

lifespan.

5.11 ■ DELIRIUM AND CATATONIA

CHAPTER 5.11 ■ DELIRIUM AND CATATONIA

DANIEL T. WILLIAMS

With a growing level of sophistication in recent years, we have come to appreciate important neurophysiologic substrates of central nervous system (CNS) dysfunction inherent in many traditional psychiatric disorders. By virtue of functional neuroimaging studies clarifying that every behavior and subjective experience has a neurophysiologic correlate, it is now well recognized that the organic versus psychiatric distinction is ultimately a semantic one, determined by our current level of neurophysiologic sophistication or lack thereof.

Perturbations of consciousness and motor function that are a byproduct of a significant change in the functional integrity of the CNS from its baseline state merit specific clinical consideration by both neurologists and psychiatrists. Two such patterns of perturbation, delirium, and catatonia, are classic neuropsychiatric syndromes. We will address here the phenomenology, evaluation, and treatment of these disorders in children and adolescents.

DELIRIUM

Delirium may be defined as a transient and usually reversible dysfunction in cerebral activity that has an acute or subacute onset and is manifest clinically by a wide array of neuropsychiatric abnormalities, including impairment of consciousness or cognition, which causes a "confusional state" (1–3). Associated symptoms may include perceptual disturbances, delusions, affective lability, disordered thought processes, sleep disturbances, and psychomotor symptoms. If there is a progression of functional derangement of consciousness from normal alertness through delirium to further impairment, the patient can decline into a state of stupor, coma, and eventually death.

Insofar as there are a variety of underlying causes of delirium in different patients, it is reasonable to consider it as a syndrome rather than a single disorder. Although the term has been used with differing connotations over the years and has many synonyms in the neurologic and psychiatric literature, it seems best for current purposes to define delirium as outlined in DSM-IV-TR (Table 5.11.1).

Predisposing Factors

Children and the elderly reportedly are at higher risk to the development of delirium under circumstances of physiologic stress (4–6). While the elderly are thought to be more vulnerable because of diminished cholinergic reserve, children are thought to be more vulnerable because of immature and evolving structural and biochemical

brain development. Intrinsic predisposing patient vulnerabilities in addition to age would include a previous delirium episode, pre-existing cognitive impairment, a CNS disorder, and increased blood–brain barrier permeability. Environmental risk factors include social isolation, sensory extremes, visual or hearing deficits, immobility, as well as environmental novelty or stress. Other risk factors include medical illness, surgery, and pharmacologic influences. Clearly, during hospitalization, there is often a confluence of these predisposing and precipitating factors.

TABLE 5.11.1

DIAGNOSTIC CRITERIA FOR DELIRIUM DUE TO…∗ (1–5)

A. Disturbance of consciousness (reduced clarity of awareness of the environment) with reduced ability to focus, sustain, or shift attention.
B. A change in cognition (such as memory deficit, disorientation, language disturbance) or the development of a perceptual disturbance that is not better accounted for by a pre-existing, established, or evolving dementia.
C. The disturbance develops over a short period of time (usually hours to days) and tends to fluctuate during the course of the day.
D. There is evidence from the history, physical examination, or laboratory findings that the disturbance is caused by the direct physiologic consequences of…∗ (1–5)
∗(1)… a general medical condition.
∗(2)… substance intoxication.
∗(3)… substance withdrawal.
∗(4)… multiple etiologies.
∗(5)… not otherwise specified.

Adapted from American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders*. 4th ed. Text Revision. Washington, DC, American Psychiatric Association, 2000.

Some of the above risk factors may be modifiable and consequently present opportunities for preventive intervention. Closer observation of patients at high risk for delirium could allow for earlier detection of emergent delirium and allow for attenuation of modifiable risk factors. Probably the most readily modifiable is medication exposure, particularly of anticholinergic medications (7). Because of the general acceptance of a tendency for children to regress under stressful circumstances, milder forms of delirium may be mistaken for simply regressive or provocative behavior. As with adults, however, undetected delirium may proceed to the point of self-injury or serious interference with medical treatment.

Paradoxically, children may have a reduced risk of postcardiotomy delirium compared to adults. Kornfeld et al. (8) reported on a sample of 119 unselected open heart patients that included 20 children who had surgical procedures for repair of congenital lesions. Only one of the children developed delirium, whereas 30% of the adults operated on for congenital repairs did. It is noteworthy that preoperative psychiatric interviews may reduce postoperative delirium and psychosis by 50% (9). Others have also reported the benefit of using preoperative psychological interventions to reduce anxiety and improve perioperative management in children

(10). A clinical consensus suggests that as the severity of pathophysiologic strain increases, so does the probability of developing a delirium (11). This is particularly true for burn patients, as well as for postoperative patients. Additional factors that are considered to foster the development of delirium include sleep deprivation, sensory deprivation, and sensory overload. Thiamine deficiency can be a risk factor for delirium in pediatric intensive care and oncology patients (12). Low serum albumin is another factor, resulting in a greater bio availability of drugs that are transmitted in the bloodstream, potentially contributing to delirium (13).

Clinical Features

Given that there is a wide variety of etiologies for delirium, it may be most useful to conceptualize delirium as a final common neural pathway that leads to its characteristic symptoms (4). These symptoms often fluctuate in intensity over a 24-hour period and may be associated with shifts between hypoactive and hyperactive states or with disruption of the sleep–wake cycle. Table 5.11.2 outlines symptoms generally associated with delirium that may be variably represented in different patients. Review of studies of delirium in adults with a variety of underlying etiologies shows that some symptoms are reported more often and more consistently than others, suggesting that there may be some core symptoms, irrespective of etiology. Postulated core symptoms include attentional deficits, memory impairment, disorientation, sleep–wake cycle disturbance, thought process abnormalities, motoric alterations, and language disturbances. Associated or noncore symptoms would include perceptual disturbances (illusions, hallucinations), delusions, and affective changes (14). The associated symptoms might reflect the impact of either specific etiologic influences or individual differences in brain circuitry and vulnerability.

TABLE 5.11.2

SIGNS AND SYMPTOMS OF DELIRIUM (“PLASTRD”)

***P*sychosis**
Perceptual disturbances (especially visual), including illusions, hallucinations, metamorphopsias
Delusions (usually paranoid and poorly formed)
Thought disorder (tangentiality, circumstantiality, loose associations)
***L*anguage Impairment**
Word-finding difficulty/dysnomia/paraphasia
Dysgraphia
Altered semantic content
Severe forms can mimic expressive or receptive aphasia
***A*ltered or Labile Affect**
Any mood can occur, usually incongruent to context
Anger or increased irritability common
Hypoactive delirium often mislabeled as depression
Lability (rapid shifts) common

Unrelated to mood preceding delirium

Sleep–Wake Disturbance
Fragmented throughout 24-hour period
Reversal of normal cycle
Sleeplessness

Temporal Course
Acute/abrupt onset
Fluctuating severity of symptoms over 24-hour period
Usually reversible
Subclinical syndrome may precede and/or follow the episode

Reactivity Altered
Hyperactive
Hypoactive
Mixed

Diffuse Cognitive Deficits
Attention
Orientation (time, place, person)
Memory (short- and long-term; verbal and visual)
Visuoconstructional ability
Executive functions

Adapted from Trzepacz PT, Meagher DF, Wise M: Neuropsychiatric aspects of delirium. In: Yudofsky SC, Hales RE (eds): *The American Psychiatric Publishing Textbook of Neuropsychiatry and Clinical Neurosciences*. 4th ed. Washington, DC, American Psychiatric Publishing, 525–564, 2002.

Some studies suggest that the motoric profile in delirium is influenced by etiology. Thus, delirium due to drug and alcohol related causes is more commonly hyperactive, whereas delirium due to metabolic disturbances, including hypoxia, is more frequently hypoactive (15,16). As yet, however, available studies have not provided clear evidence that gross motoric subtypes have discernible neurobiologic mechanisms.

Mortality rates during a hospitalization involving delirium for adults have ranged from 1.5% to 65% in different case series (17). Turkel and Tavare (18) retrospectively reviewed 84 children and adolescents with delirium, among 1,027 consecutive inpatient psychiatric consultations during a 4-year period. They found a mortality rate of 20% and a prolonged length of stay when delirium was documented. It is clear therefore that the diagnosis of delirium constitutes a matter of severe medical urgency. Since some of the medical conditions contributing to delirium are potentially reversible, early clarification of diagnosis and aggressive initiation of treatment are clinically imperative.

Etiology

When a diagnosis of delirium is established, a thorough search for causes must be pursued, insofar as correction or amelioration of specific underlying causes is important in reversing the condition. However, this process of investigation should not unduly delay prompt treatment of the delirium itself, since such treatment can

reduce symptoms even before the underlying medical causes have been reversed. As noted above, from a DSM-IV-TR perspective, delirium is broadly categorized according to etiology into five groups. These include delirium due to a general medical condition, due to substance use or withdrawal, due to multiple causes, and due to no apparent cause that can be identified. It is probably useful to spell out in more detail a list of the wide variety of etiologies that may pertain, either individually or in combination. These are listed in Table 5.11.3.

Delirium in children and adolescents involves the same categories of etiologies as adults, though the relative frequency of specific etiologies differs. Thus, delirium related to illicit drugs is more common in the child and adolescent age group, as is the incidence of delirium from hypoxia due to foreign-body inhalation, drowning, and asthma, as well as delirium related to head trauma.

Differential Diagnosis

Delirium frequently goes undetected in a variety of therapeutic settings by a variety of medical specialists, including neurologists and psychiatrists (19). Failure of detection may derive from insidious onset and fluctuating course involving multiple symptom constellations that can generate much clinical variability. Thus an agitated, hyperactive delirium, that is more likely to be recognized, contrasts with the more common, mixed or hypoactive symptom pattern that may be more readily overlooked. This is particularly true in a hospital setting, with multiple shift changes of staff, where subtle and gradual changes of mental status may not be discerned. Diagnosis can be improved by routinely assessing cognitive function, by improving staff awareness of the varied presentations of delirium, and by using one of the screening instruments for delirium currently available (4).

Differential diagnosis includes depression, psychosis, anxiety, somatoform disorders, dementia (more commonly in the elderly and particularly in children), behavioral disturbance. Because of the general tendency for children to regress under stressful circumstances, milder forms of delirium may be mistaken for simply regressive or provocative behavior. As with adults, however, undetected delirium may proceed to the point of self-injury or serious interference with medical treatment. Effective diagnosis requires close attention to symptom pattern, temporal sequence, and objective clinical test results (laboratory, cognitive, electroencephalographic). Since delirium is often the first indication of serious medical deterioration, any patient manifesting an abrupt decline in attentional or cognitive function should be evaluated for possible delirium.

TABLE 5.11.3

ETIOLOGIES OF DELIRIUM

Drug intoxication

Intracranial infection Drug withdrawal Systemic infection Metabolic/endocrine disturbances Cerebrovascular disorder Traumatic brain injury Organ insufficiency Seizures Other CNS etiologies Neoplastic disease Other systemic etiologies
Adapted from Hales RE, Yudofsky SC: *The American Psychiatric Publishing Textbook of Neuropsychiatry and Clinical Neurosciences*. 3rd ed. Washington, DC, American Psychiatric Press, 2002.

Assessment

To allow more accurate diagnosis and monitoring, more than 10 different assessment instruments suitable for adults have been developed (20). One of these, the delirium rating scale, has been systematically evaluated retrospectively with 84 children and adolescents diagnosed with delirium (age range 6 months to 19 years) (21). The delirium rating scale is composed of 10 items: two items ascertain the temporal onset of symptoms and their relationship to a physical disorder; eight other items evaluate major symptoms of delirium. These eight items rate perceptual disturbances, hallucinations, delusions, changes in psychomotor behavior, diffuse cognitive dysfunction, disturbances of sleep–wake cycle, lability of mood, and variability of symptoms. The cognitive dysfunction item includes impairment of attention, concentration, and memory. The results of the Turkel et al. study (21) suggest that the delirium rating scale can be used effectively to evaluate delirium in the pediatric population.

In most cases, electroencephalograms (EEGs) are not needed to make a clinical diagnosis of delirium, but are used when seizures are suspected or when differential diagnosis is difficult. The degree of slowing on EEGs recorded serially over time in children and adolescents correlates with the severity of, and recovery from, delirium (22).

The psychiatrist will clearly not be primarily responsible for diagnosing and managing the underlying medical condition contributing to the delirium. However, supportively maintaining the morale and involvement of family members who can be invaluable observers and informers to the medical staff regarding the patient's mental status can be a vital part of the consulting psychiatrist's function. This, of course, is supplementary to the psychiatrist's own longitudinal assessments of the patient, which should be documented systematically.

Treatment

Prompt treatment is vital because of the substantial morbidity and mortality associated with delirium. Symptomatic treatments include medication, environmental manipulation, as well as patient and family psychosocial support (11). These should be initiated concomitant with the attempts to identify and reverse underlying causes of the delirium.

Pharmacologic treatment with a neuroleptic, most commonly haloperidol, is the most commonly reported medical intervention for delirium, despite the absence of double-blind, placebo-controlled trials documenting efficacy. Haloperidol can be given orally, intramuscularly, or intravenously, although haloperidol is not approved by the U.S. Food and Drug Administration for intravenous use. Clinical experience with haloperidol in pediatric delirium supports its beneficial effects, although purely based on uncontrolled case reports (23). Based on such existing clinical experience, one suggested dosage regimen for children younger than 4 years of age starts with 0.25 mg slowly intravenously over 30 to 45 minutes as a loading dose, and 0.05 to 0.5 mg/kg/24 hr intravenously as a continuing dose. When using higher doses of IV haloperidol (e.g., >20 mg/day), electrocardiographic tracking of QTc interval prolongation and other relevant parameters should be done daily, as well as monitoring and correction of magnesium, phosphate, and other electrolytes in order to minimize the risks of cardiotoxicity (up to torsade de pointes and other tachyarrhythmias). The oral dose of haloperidol is twice the intravenous dose. Although no fixed dosing schedule based on controlled studies is available for either children or adults, a protocol for haloperidol use in agitated delirium in adults has been proposed (11). Intravenous administration of haloperidol is reportedly associated with fewer extrapyramidal symptoms compared with oral administration (24). The rationale for this neuroleptic treatment intervention is based on clinical evidence suggesting a low cholinergic, excess dopaminergic state as the final common neural pathway for delirium (4).

Benzodiazepines are generally reserved for delirium due to alcohol or sedative–hypnotic withdrawal. Occasionally, lorazepam may be used as an adjunct with haloperidol in cases of delirium where agitation and insomnia persist. Caution is needed, however, to avoid over-sedation or paradoxical disinhibition.

Environmental interventions for delirium are often helpful but are not by themselves adequate treatment. Family members and nurses can help reorient the patient with a clock, calendar, and familiar objects. A room with a window can help with diurnal cues and adequate lighting at night can diminish frightening visual misperceptions. Encouraging a stable parent to stay overnight, with appropriate explanation to the parent about the phenomenon of delirium and about the merits of supportive measures for the patient, can be quite reassuring.

Psychiatrists are often called to evaluate the fluctuating, confusing, and bizarre behaviors that may characterize delirium. Insofar as significant morbidity and mortality can be associated with this condition, it is important for the psychiatrist to

help organize a systematic differential diagnosis, collaborate with the primary care physician in identifying the underlying cause(s), and help formulate a plan for monitoring and treating the associated agitation as well as related psychiatric symptomatology in both the patient and family.

CATATONIA

In contrast to delirium, which is defined primarily by alterations in level of consciousness as reflected by attention and cognition, with occasionally accompanying psychomotor symptoms, catatonia is defined by a cluster of motor symptoms, including a rigid posture, mutism, fixed staring, stereotypic movements, hyperkinetic movements, or stupor. Implicit in this varied constellation of motor symptoms, however, is the presumption of an underlying neuropsychiatric derangement which presents the clinician with a differential diagnostic and treatment challenge of comparable complexity to that posed by delirium. Like delirium, catatonia is best understood as a syndrome that may be associated with a wide array of psychiatric and medical disorders that lead to the final common path of these motor manifestations. In some patients, the differential diagnostic challenge will include differentiating between delirium and catatonia.

In the current diagnostic classification nomenclature of the American Psychiatric Association, there are three domains in which catatonia is represented and these are represented in Tables 5.11.4 to 5.11.6. This diverse representation speaks to the multifactorial contributants to this syndrome from diverse etiologies.

Predisposing Factors

By definition in the existing psychiatric nomenclature, predisposing factors to catatonia include the three clinical domains referred to above, namely a variety of medical conditions, a variety of mood disorders, and a particular type of schizophrenia. Although the occurrence of catatonia in children and adolescents is well documented in the clinical literature (25), there are no epidemiologic studies that indicate a relative difference in incidence associated with age (26). It appears that the range of primary diagnoses with which catatonia is associated in youngsters broadly overlaps that reported in adults. In addition, there are a significant number of reports of catatonia associated with autism, the Prader–Willi syndrome, and intellectual disability (27,28). As with delirium, catatonia in youngsters may be more difficult to diagnose because of the more limited expressive capacity of children and adolescents, as well as the tendency of observers to ascribe symptomatic behavior to willful regression of an oppositional nature.

TABLE 5.11.4

DSM-IV-TR CRITERIA FOR CATATONIC DISORDER DUE TO… [INDICATE THE GENERAL MEDICAL CONDITION]

A. ***Cat***atonia is manifested by motoric immobility, excessive motor activity (that is apparently purposeless and not influenced by external stimuli), extreme negativism or mutism, peculiarities of voluntary movement, or echolalia or echopraxia. B. ***Med:*** There is evidence from the history, physical examination, or laboratory findings that the disturbance is the direct physiologic consequence of a general medical condition. C. ***Not Ment:*** The disturbance is not better accounted for by another mental disorder (e.g., a manic episode). D. ***Not Del:*** The disturbance does not occur exclusively during the course of a delirium.
Adapted from American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders*. 4th ed., Text Revision. Washington, DC, American Psychiatric Association, 2000.

TABLE 5.11.5

DSM-IV-TR CRITERIA FOR CATATONIC FEATURES SPECIFIER OF A MOOD DISORDER

Specify if: **With Catatonic Features** (can be applied to the current or most recent major depressive episode, manic episode, or mixed episode in major depressive disorder, bipolar I disorder, or bipolar II disorder) The clinical picture is dominated by at least two of the following characteristics (***MUMEE***) (1) ***M***otoric immobility as evidenced by catalepsy (including waxy flexibility) or stupor (2) ***U***tmost negativism (an apparently motiveless resistance to all instructions or maintenance of a rigid posture against attempts to be moved) or mutism (3) ***M***otor hyperactivity (i.e., apparently purposeless and not influenced by external stimuli) (4) ***E***ccentricities of voluntary movement as evidenced by posturing (voluntary assumption of inappropriate or bizarre postures), stereotyped movements, prominent mannerisms, or prominent grimacing (5) ***E***cholalia or echopraxia
Adapted from American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders*. 4th ed. Text Revision. Washington, DC, American Psychiatric Association, 2000.

TABLE 5.11.6

CATATONIC TYPE OF SCHIZOPHRENIA

A type of schizophrenia in which the clinical picture is dominated by at least two of the following characteristics (***MUMEE***): (1) ***M***otoric immobility as evidenced by catalepsy (including waxy flexibility) or stupor (2) ***U***tmost negativism (an apparently motiveless resistance to all instructions or maintenance of a rigid posture against attempts to be moved) or mutism (3) ***M***otor hyperactivity (i.e., apparently purposeless and not influenced by external stimuli) (4) ***E***ccentricities of voluntary movement as evidenced by posturing (voluntary assumption of inappropriate or bizarre postures), stereotyped movements, prominent mannerisms, or prominent grimacing (5) ***E***cholalia or echopraxia

Clinical Features

The principal motor signs associated with catatonia are mutism, immobility, negativism, posturing, stereotypy, and echophenomena. Although DSM-IV-TR

defines a requirement for two of these to be present in cases of mood disorder or schizophrenia, it does not specify a duration. Some clinicians advocate that these signs be present for at least an hour or be reproducible on at least two occasions (29). Prolonged immobility may generate malnutrition, dehydration, weight loss, muscle wasting, contractures, and bedsores. Death may ensue from venous thrombosis and pulmonary emboli. A summary description of clinical features frequently associated with catatonia is presented in Table 5.11.7.

Etiology

As with delirium, there have been efforts to define a final common neurophysiologic pathway, whereby many different pathophysiologic conditions may contribute to the clinical features of catatonia. Recent views implicate frontal lobe circuitry dysfunction (29). Disruption of connections from perceptual-integrating brain systems because of thalamic or parietal lobe lesions as well as limbic interference (as occurs in certain mood states) have been postulated to play etiologic roles. The neurotransmitters dopamine and GABA have been implicated and this has therapeutic relevance.

As previously noted, conditions in which catatonia is expressed include mood disorders, psychosis, and a variety of medical conditions, including neurologic disorders, metabolic disorders, as well as drug intoxication and withdrawal.

Catatonia has been reported in about 15% of manic episodes in adult patients with bipolar mood disorders, with one series of 99 manic patients finding as high as a 27% incidence (30). Bipolar mood disorder is the most common cause of catatonia. Depression is the second most common condition underlying catatonia in adults. Catatonia in depressed patients is often manifest as profound psychomotor retardation, sometimes progressing to stupor or pseudodementia. Delay in diagnostics and treatment intervention for treating catatonia in mood disorder patients clearly can increase morbidity and mortality.

Schizophrenia accounts for about 10% of adult patients with catatonia (31). Catatonic features more commonly encountered in these patients include catalepsy, mannerisms, posturing, and mutism. Historically, this diagnosis has been invoked more frequently than that of mood disorder in patients with catatonia, which is a disservice if it leads to premature or exclusive reliance on neuroleptic medication, with associated increased risks of disabling side effects. (These side effects can include neuroleptic malignant syndrome [NMS], an admittedly rare complication that can initially be difficult to differentiate from catatonic schizophrenia.)

TABLE 5.11.7

PRINCIPAL FEATURES OF CATATONIA

Feature	Description

Mutism	Verbal unresponsiveness, not always associated with immobility.
Stupor	Unresponsiveness, hypoactivity, and reduced or altered arousal during which the patient fails to respond to queries; when severe, the patient is mute, immobile, and does not withdraw from painful stimuli.
Negativism (Gegenhalten)	Patient resists examiner's manipulations, whether light or vigorous, with strength equal to that applied, as if bound to the stimulus of the examiner's actions.
Posturing (catalepsy)	Maintains postures for long periods. Includes facial postures, such as grimacing or *Schnauzkrampf* (lips in an exaggerated pucker). Body postures, such as *psychological pillow* (patient lying in bed with his head elevated as if on a pillow), lying in a jackknifed position, sitting with upper and lower portions of body twisted at right angles, holding arms above the head or raised in prayer-like manner, and holding fingers and hands in odd positions.
Waxy flexibility	Offers initial resistance to an induced movement before gradually allowing himself to be postured, similar to bending a candle.
Stereotypy	Non–goal-directed, repetitive motor behavior. The repetition of phrases and sentences in an automatic fashion, similar to a scratched record, termed *verbigeration*, is a verbal stereotypy. The neurologic term for similar behavior is *palilalia*, during which the patient repeats the sentence just uttered, usually with increasing speed.
Automatic obedience	Despite instructions to the contrary, the patient permits the examiner's light pressure to move his limbs into a new position (posture), which may then be maintained by the patient despite instructions to the contrary.
Ambitendency	The patient appears "stuck" in an indecisive, hesitant movement, resulting from the examiner verbally contradicting his own strong nonverbal signal, such as offering his hand as if to shake hands with stating, "Don't shake my hand; I don't want you to shake it."
Echophenomena	Includes *echolalia*, in which the patient repeats the examiner's utterances, and *echopraxia*, in which the patient spontaneously copies the examiner's movements or is unable to refrain from copying the examiner's test movements, despite instruction to the contrary.
Mannerisms	Odd, purposeful movements, such as holding hands as if they were handguns, saluting passerby, or exaggerations or stilted caricatures of mundane movements.

Reprinted from Fink M, Taylor MA: *Catatonia. A Clinician's Guide to Diagnosis and Treatment*. New York, Cambridge University Press, 2003, with permission.

Many general medical conditions can manifest with catatonia, including many of the same conditions that are associated with delirium. These include a variety of neurologic syndromes, metabolic, autoimmune, and endocrine disorders, infections, burns, and drug-induced states. The latter may include both recreational and prescribed drugs, including NMS. Neurologic conditions and metabolic disorders associated with catatonia are outlined in Tables 5.11.8 and 5.11.9.

A review of the literature regarding catatonia in children and adolescents suggests that signs of catatonia in youngsters are similar to those in adults (29). It appears that catatonia is sufficiently frequent in this age group that children and adolescents with otherwise unexplained motor symptoms should be formally assessed for it.

Differential Diagnosis

The first task in diagnosis is recognizing the constellation of motor symptoms that constitute catatonia. If, after initial evaluation, there is no clear etiology, it is often diagnostically helpful to administer an intravenous infusion of lorazepam in a medically supervised setting. Because of the possibility of respiratory depression, facilities for assisted respiration should be available. In either adolescents or adults, intravenous infusion of lorazepam, 0.1 mg/kg, with a maximum dose of 1 to 2 mg, can be infused over 2 minutes. This is often helpful in alleviating mutism, posturing, and rigidity. The infusion should be accompanied by supportive communication to the patient of the prospect of benefit of this intervention. A positive response, including relaxation of posture, improvement or restoration of speech, diminished mannerisms, and responsiveness to commands would confirm the diagnosis of catatonia (29). There is insufficient data to allow for an advisory on dosage of diagnostic intravenous infusion in children with catatonia, although one may be influenced in this regard by the dose range indicated for treatment of status epilepticus (maximum pediatric dose of 0.32 mg/kg/day, as specified by the Physician's Desk Reference).

When catatonia is ascertained in a child or adolescent, the differential diagnosis regarding underlying etiology in order of decreasing frequency is mood disorder, seizure disorder, pervasive developmental disorder, and schizophrenia, followed by other neurologic and metabolic disorders, including the effects of psychoactive substances (29). Although some underlying etiologies can be clarified by laboratory tests, catatonia secondary to a mood disorder or a schizophreniform disorder has no pathognomonic laboratory correlate. In those cases, personal and family history, most often with input from parents or other informants, is crucial in establishing the psychiatric diagnosis.

EEGs can be diagnostic if an epileptiform disorder is presenting as catatonia. The EEG will be diagnostic in these cases if obtained during the symptomatic episode, but not necessarily if administered interictally. Clearly, if there are indications that there may be nonpsychiatric contributants to the catatonia, it is imperative that a neurologist and often other primary care physicians become involved in the medical workup seeking to define the underlying etiology.

TABLE 5.11.8

NEUROLOGIC CONDITIONS ASSOCIATED WITH CATATONIA

Encephalitis
Postencephalitic states
Parkinsonism
Subacute sclerosing panencephalitis
Bilateral lesions of the globus pallidus
Bilateral infarction of the parietal lobes
Temporal lobe infarction
Thalamic lesions
Periventricular diffuse pinealoma
Anterior cerebral and anterior communicating artery aneurysms and hemorrhagic infarcts
Frontal lobe traumatic contusions, arteriovenous malformations, neoplasms

Primary frontal lobe degeneration Traumatic hemorrhage in the region of the third ventricle Subdural hematoma General paresis Tuberous sclerosis Paraneoplastic encephalopathy Multiple sclerosis Pediatric autoimmune neuropsychiatric disorder associated with streptococcal infections (PANDAS) Familial cerebellar-pontine atrophy Epilepsy (particularly psychosensory) Creutzfeldt–Jakob disease Alcohol degeneration and Wernicke encephalopathy AIDS-related dementia and other white matter dementias Narcolepsy
Adapted from Fink M, Taylor MA: *Catatonia. A Clinician's Guide to Diagnosis and Treatment*. New York, Cambridge University Press, 2003.

Conditions that can be mistaken for catatonia include elective mutism, involving conscious and volitional withholding of speech. However, elective mutism is generally not accompanied by any of the motor signs needed for the diagnosis of catatonia. Juvenile Parkinson disease (PD) can present in childhood or adolescence with bradykinesia (slowing of movement) and bradyphrenia (slowing of cognition). However, PD will often include tremor, pill-rolling finger movements, a shuffling gait, and does not present with bizarre posturing or mutism. Torsion dystonia may present with seemingly bizarre posturing and indeed is often initially misdiagnosed as a psychiatric disorder, but is generally not associated with mutism and will be readily diagnosable by a neurologist familiar with this movement disorder. Somatoform disorder should also be considered in the differential diagnosis, with a different personal and family history pattern, as well as atypical physical presentations often being helpful in the differential (32).

Delirium and its devolution to stupor will often present with reduced CNS arousal that is also a hallmark of catatonia. Indeed, as noted above, some of the neurologic and metabolic conditions that can generate either delirium or catatonia can also generate the other. The diagnostic distinction between these two syndromes is at this point primarily phenomenologic. Delirium is defined by the primary presenting deficits in the areas of consciousness, attention, and cognition, while variable alterations in motor function, generally considered to be associated phenomena, are not necessarily present. Catatonia is defined by the primary presenting deficits in motor function, often with preservation of awareness and memory, as demonstrable on resolution of the catatonic state, when patients can often reproduce conversations and observations that occurred during the catatonic state. Undoubtedly there are some patients in which these syndromes may coexist, though the frequency of this is not clearly documented in the clinical literature. The clinician's primary task, after defining and documenting the presenting phenomenology, is to actively search for the underlying etiology in an effort to delineate routes of treatment intervention and symptomatic resolution.

TABLE 5.11.9

METABOLIC DISORDERS ASSOCIATED WITH CATATONIA

Diabetic ketoacidosis
Hyperthyroidism
Hypercalcemia from a parathyroid adenoma
Pellagra, vitamin B_{12} deficiency
Acute intermittent porphyria
Endocrinopathies: Addison disease, Cushing disease
Syndrome of inappropriate antidiuretic hormone secretion
Hereditary coproporphyria, porphyria
Homocystinuria, uremia, glomerulonephritis
Hepatic dysfunction or encephalopathy
Thrombocytopenic purpura
Lupus erythematosus or other causes of arteritis
Infectious mononucleosis
Bacterial infections: tuberculosis, typhoid, malaria
Langerhans carcinoma
Toxic states secondary to mescaline, amphetamine, phencyclidine, cortisone, disulfiram, aspirin, antipsychoticagents, illuminating gas, organic fluorides

Adapted from Fink M, Taylor MA: *Catatonia. A Clinician's Guide to Diagnosis and Treatment*. New York, Cambridge University Press, 2003, with permission.

Assessment

Rating scales have value both for enhancing precision in documenting clinical symptoms as well as for teaching and clinical research purposes. There are several rating scales available for catatonia with good reported interrater reliability (33–35). The Stony Brook scale (33) has a reported interrater reliability of 0.9 and is easy to administer in a simpler version for screening purposes as well as in a more detailed version for rating severity.

Treatment

As with any serious medical condition, early diagnosis and prompt, effective treatment diminishes morbidity and mortality. The clinical literature documents that there have often been unfortunate delays in both of these domains. Insofar as patients with catatonia need protection, intensive treatment, and close monitoring, this is usually best administered in a hospital setting. The number and pattern of catatonic symptoms do not predict response to treatment, but clinical data suggest that most patients respond well to treatment, with prognosis strongly influenced by that of the underlying etiology.

Different treatment algorithms have been outlined for different varieties of catatonia (29). Patients with "retarded catatonia" often present in a stuporous state or with rigid posture. They may become dehydrated and nutrition may be compromised. If untreated for extended periods, bedsores and contractures may develop.

Supportively explaining to family members the diagnosis and need for prompt treatment is a top priority. Restoration and maintenance of hydration with intravenous fluid and electrolytes is often necessary, with appropriate EKG monitoring. If antipsychotic drugs have been previously in place without benefit, they are best discontinued to avoid precipitating or perpetuating a neurotoxic effect. If a specific etiology is identified, its treatment takes priority (e.g., nonconvulsive status epilepticus). If no such cause is identified, treatment is started with a benzodiazepine, most often lorazepam, and most often initially by the intravenous route (36,37). As noted earlier, an intravenous infusion of lorazepam, 0.1 mg/kg, with a maximum dose of 1 to 2 mg, can be infused over 2 minutes with adolescents or adults. If there is a positive response with symptom attenuation, one shifts to a maintenance dose geared to sustain and enhance improvement, with a maximum pediatric dose of 0.32 mg/kg/day specified by the Physician's Desk Reference (the dose indicated for treatment of status epilepticus). For adolescents, one will often start with a daily dose of 3 to 4 mg. If improvement is only partial, the dose can be titrated within a few days to 8 to 16 mg/day (38). If clinical status stabilizes and improves on this benzodiazepine regimen, one addresses further the issues of nutrition, physical rehabilitation, and treatment of the underlying etiologic influences. If, however, response remains inadequate after a few days, ECT becomes the treatment of choice (29).

TABLE 5.11.10

MANAGEMENT FOR MALIGNANT CATATONIA/NEUROLEPTIC MALIGNANT SYNDROME

Goal	Measures to Take
Reverse hyperthermia	Aspirin or acetaminophen suppositories; place patient under cooling blankets or give alcohol bath; gastric lavage with ice water.
Reverse dehydration	Intravenous normal or half normal saline. Ringer lactate is avoided as it may increase acidosis. Glucose loads may precipitate a Wernicke encephalopathy in a chronic alcoholic or other persons with chronically low thiamine levels.
Maintain stable blood pressure and cardiac rhythm	Blood pressure and pulse rate are monitored. Hyperkalemia from muscle breakdown is prevented or resolved. Hypertension is controlled with labetalol or esmolol; hypotension by increasing blood volume, and giving vasopressors.
Ensure adequate oxygenation	Continuously monitor oxygen saturation. Maintain airway artificially if rigidity blocks air exchange. Use 100% oxygen if oximetry shows blood saturation less than 95%.
Avoid complications of immobility: thrombosis, embolism, aspirationpneumonia, bedsores	Critical care nursing, moving of limbs, changing of position, skin care.
Avoid renal failure	Frequent monitoring of serum creatinine phosphokinase (as an indicator of muscle necrosis), creatine, and urea nitrogen. Check urine for myoglobinuria to monitor renal function. Dialysis may be required if the syndrome is not promptly and fully resolved.

Reprinted from Fink M, Taylor MA: *Catatonia. A Clinician's Guide to Diagnosis and Treatment*. New York, Cambridge University Press, 2003, with permission.

Patients with "excited catatonia," including patients with "delirious mania," are a potential danger both to themselves and to others, frequently requiring not only hospitalization but physical restraints and isolation. If no specific treatable etiology can be identified, aggressive treatment with a benzodiazepine is recommended. A common protocol with adolescents or adults is 1 to 2 mg of lorazepam IV every 20 to 30 minutes, up to 10 mg within a few hours (38). If this intervention is not rapidly effective, daily or twice-daily ECT for several days may be needed to achieve stabilization.

"Malignant catatonia" is a life-threatening condition with many features of catatonia plus fever and autonomic instability. Some consider NMS to be a variant and the most common current presenting manifestation of malignant catatonia, precipitated by neuroleptics (29). The first treatment interventions for malignant catatonia/NMS should be the stopping of neuroleptics, the physical protection of the patient when agitated, control of temperature and hydration, as well as close medical monitoring of vital signs in a hospital setting (Table 5.11.10). Two alternative treatment approaches have evolved for management of this disorder. The dopaminergic-muscle relaxant approach considers NMS to be an idiosyncratic response to the dopamine blockade that is generated by neuroleptics. This formulation led to a treatment strategy using the presynaptic dopamine agonist amantadine; the postsynaptic dopamine receptor agonist bromocriptine; and the muscle relaxant dantrolene (39). An alternate strategy involves the benzodiazepine/ECT approach which is a variant of that described above in the treatment of excited catatonia (29,40). Finally, conservative management consisting of stopping potentially offending agents and hydrating vigorously has also been endorsed by some. Controlled studies are needed to clarify the preferred management strategy for NMS.

Once a patient has recovered from an acute episode of catatonia, current advisories call for a maintenance dose of benzodiazepine for at least 6 months. Recurrence of catatonia requires dose augmentation and the possible use of ECT (29).This maintenance recommendation is a supplement to the designated treatment strategy addressed to the patient's underlying clinical condition.

CONCLUSIONS

Delirium and catatonia are neuropsychiatric conditions representing perturbations of consciousness and motor function that are byproducts of significant changes in the functional integrity of the CNS. It is vital that child and adolescent psychiatrists be familiar with the phenomenology, assessment, differential diagnosis, and treatment of

these syndromes, insofar as early diagnosis and treatment intervention can have significant impact on the patient's survival and prognosis for future functioning.

5.12 ELIMINATION DISORDERS

CHAPTER 5.12 ■ ELIMINATION DISORDERS: ENURESIS AND ENCOPRESIS

EDWIN J. MIKKELSEN

ENURESIS

Definition and Historical Note

Enuresis is divided into two subtypes: primary and secondary. Primary enuresis encompasses children who have never achieved continence, whereas secondary enuresis refers to those children who maintain continence for at least 1 year, only to lose it at some point after that. The term itself is derived from the Greek word *enourein,* "to void urine," and has come to imply nocturnal events, although that connotation is not inherent in the derivation of the word itself. There is a rich literature concerning enuresis and its treatment over the centuries. In retrospect, many of these treatment approaches now appear to have been quite sadistic. This history has been summarized in an excellent review by Glicklich (1), which covers material dating back to the Ebers Papyrus of 1550 BC.

There has been substantial progress in the treatment of enuresis, which in turn has contributed to a greater understanding of the fundamental pathophysiologic processes involved. These advances are reviewed in this chapter.

Prevalence and Epidemiology

Statistics concerning the prevalence of enuresis also must take into account the severity of the disorder. For example, in the Isle of Wight Study, Rutter and colleagues (2) found that 15.2% of boys were wet less often than once a week, whereas only 6.7% wet at least once a week. The corresponding figures for girls were 12.2% and 3.3%, respectively. By the age of 14 years, only 1.9% of boys were wet less often than once a week, and 1.1% were wetting at least once a week, with the corresponding figures for girls being 1.2% and 0.5%, respectively (3). Longitudinal data from the Isle of Wight Study have illustrated that wetting develops in many children between the ages of 5 and 7 years. Enuresis also was found in greater frequency in children undergoing psychosocial stress and in those living in socially disadvantaged circumstances (2).

A Scandinavian study of 3,206 7-year-old children found an overall prevalence of 9.8%; 6.4% of this group was accounted for by children with night wetting, 1.8% by day wetters, and 1.6% by those with mixed day and night wetting. This study also showed a strong genetic influence in that the risk of a child having enuresis was 7.1

times greater if the father manifested enuresis after 4 years of age, and 5.2 times greater if the mother did (4).

An 8-year longitudinal study in New Zealand found a prevalence of 7.4% for nocturnal enuresis in 8 year olds. This figure was accounted for by 3.3% with primary enuresis and 4.1% with secondary enuresis (5).

More recent studies have found remarkably similar results. In a group of 392 7-year-old children from Sweden, Wille (6) reported a prevalence of 7.3% for monosymptomatic primary enuresis. A questionnaire study involving a large cohort of Australian children in the 5- to 12-year-old range reported an overall incidence of 5.1% for nocturnal enuresis of at least weekly frequency and 1.4% for daytime wetting of similar frequency (7). In a population-based questionnaire study, Soderstrom et al. (8) reported bedwetting at a frequency of at least once per month in 7.1% of first-graders, and 2.7% of fourth-graders.

Clinical Description

As noted, the term enuresis itself denotes only the voiding of urine, but over the years, it has acquired both a pathologic and a nocturnal connotation. Daytime wetting is correctly referred to as diurnal enuresis, whereas nighttime wetting is referred to as nocturnal enuresis.

In the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5*),* the American Psychiatric Association (2013) defines primary enuresis as "repeated voiding of urine during the day or at night into bed or clothes, whether involuntarily or intentionally." The DSM-5 goes on to specify that "the behavior is clinically significant as manifested by either a frequency of at least twice per week for at least three consecutive months or impairment in social, academic (occupational) or other important areas of functioning." The child must also have reached an age at which continence could reasonably be expected. The criteria require a chronologic age of 5 years as a cutoff or a mental age of 5 years for those children with developmental delays. The DSM-5 also stipulates that the wetting not be the result of "the physiological effects of a substance (e.g., a diuretic, an antipsychotic agent) or a general medical condition (e.g., diabetes, spina bifida, a seizure disorder)." Three subtypes of enuresis are defined: nocturnal only (nighttime wetting), diurnal only (daytime wetting), and nocturnal and diurnal (mixed day and night wetting). A distinction also is made between primary and secondary enuresis. Primary enuresis refers to those children who have never achieved urinary continence, whereas secondary enuresis refers to those children who have achieved continence and then lost it. The period of continence necessary to differentiate between primary and secondary enuresis had variously been proposed to be 6 months to 1 year. The criteria do not specify a precise period of time for the distinction, but instead makes reference to "a secondary type in which the disturbance develops after

a period of established urinary continence." A child is not considered to have primary functional enuresis until 5 years of age. Secondary enuresis can begin at any time, once the criterion of initial continence has been fulfilled, but the usual onset is between 5 and 7 years of age (2). These criteria are essentially unchanged from the prior edition of the DSM. It is unfortunate that the inclusion of the term "involuntarily or intentionally" has been continued, as the number of children whose incontinence is involuntary or intentional is quite small.

Etiology and Pathogenesis

The physiologic manifestations of this disorder have led to a wide range of etiologic theories. A primary focus of these studies has naturally been the anatomy of the bladder and urinary tract. A study that investigated bladder capacity in children with primary nocturnal enuresis, former enuretic patients, and control subjects, failed to find any significant difference in bladder capacity between the groups (9). It also has been demonstrated that fluid loading can produce enuretic events in children who do not have a history of enuresis (10,11). Children with enuresis were found to have developmental delays twice as often as those without in a large longitudinal population study (12) and Touchette et al. (13) have reported an association between bedwetting and related developmental milestones. An investigation of event-related potentials and brainstem auditory-evoked responses found longer latencies in children with enuresis, as compared to controls, which the authors interpreted as evidence of a maturational delay (14).

There is an obvious relationship between enuresis and bladder infection (15); thus, an infection of the urogenital tract should be ruled out before a diagnosis of functional enuresis is made. This is especially important for girls, who are more prone to urinary tract infections (16). The possibility of urinary tract obstruction as a widespread cause of enuresis has been reported (17) but has been criticized because such a hypothesis can lead to unnecessary surgery (18). After extensively reviewing the literature on this subject, Shaffer (19) concluded: "There is no evidence that urethral dilatation or bladder neck repair is an effective treatment for enuresis." The only exception to this would be if there were very specific pathophysiologic findings.

Other investigations into the role of urodynamic abnormalities in the pathogenesis of primary enuresis support Schaffer's conclusion (20). In a large study, Kawauchi et al. (21) found an incidence of urologic abnormalities of 1.8% on intravenous pyelography (n = 940), 7.1% on voiding cystourethrography (n = 695), 11.5% on cystometry (n = 487), and no abnormalities on renal ultrasonography (n = 58). Of those who did manifest reflux on voiding cystourethrography, the degree of reflux was assessed as mild in 92.1%.

Yeung et al. (22) utilized noninvasive ultrasound techniques to assess physiologic bladder parameters in 514 children with primary enuresis (age 5 to 18 years; mean

age 11.2 years), and 339 age-matched controls. Analysis of the data from the entire study group yielded three subtypes: small-capacity bladder with thick wall; normal-capacity bladder with normal wall thickness; and large-capacity bladder with thin wall. There was also a 4-week period of treatment with desmopressin acetate (DDAVP) for the children with enuresis. The authors found that "poor response to treatment was significantly associated with pathological bladder conditions, that is, small-capacity bladder with thick bladder wall or large-capacity bladder with thin bladder wall."

The nature of the enuretic phenomenon has naturally led to speculation concerning a psychodynamic etiology. These hypotheses have in general evolved from case reports or have been derived from theoretical considerations. There has been one rigorous attempt to define the generalizations derived from the literature regarding enuresis and encopresis and then to determine with what frequency these generalizations were borne out by an analysis of the clinical material. This elegant study by Achenbach and Lewis (23) revealed that "only two of the twenty-four generalizations derived from the literature regarding encopresis and enuresis received support at the conventional level (probability = 0.05) of statistical significance."

Epidemiologic studies have, however, shown a correlation between psychological disturbance and enuresis, which is more pronounced in older children (2). This observation then raises the question of the nature of the relationship: Is it a causal, incidental, or secondary relationship? The aforementioned link between enuresis and developmental delays, which are also linked to psychopathology, would suggest that there is a common underlying maturational factor that predisposes vulnerable children to manifest both behavioral disturbances and enuresis. In further support of this hypothesis are the observations that the nature of the behavioral disturbance in children with enuresis is nonspecific (24) and that no physiologic marker can be found that reliably differentiates psychologically disturbed from nondisturbed children with enuresis (25). Biederman et al. (26) have evaluated the possible linkage between enuresis and attention-deficit hyperactivity disorder (ADHD). Their findings indicated that enuresis did not increase the risk for psychopathology in children with or without ADHD but was associated with increased risk for learning disability in normal control children, but not in those with ADHD. Baeyens et al. (27) investigated the prevalence of ADHD in 120 children (age 6 to 12 years) with primary enuresis, utilizing parent and teacher questionnaires as well as diagnostic interviews. Their results indicated that 15% met the criteria for ADHD, and a further 22.5% met the criteria for ADHD-inattentive type. A 2-year follow-up study of the same cohort indicated that 73% of those diagnosed with ADHD had the diagnosis reconfirmed at the follow-up (28). The authors also noted that the odds of a child with ADHD still having episodes of nocturnal enuresis at 2-year follow-up were 3.2 times higher than those for a child who did not have

comorbid ADHD. The association with behavioral disturbance has been reported as being greater for secondary enuresis (29,30) and for enuresis persisting into adolescence (31). One study that specifically evaluated risk factors for the development of secondary enuresis found that delayed attainment of initial nocturnal continence and exposure to four or more stressful life events in a year were significantly related to the development of secondary enuresis (32). Similar results with regard to the relationship between psychosocial stress and secondary enuresis have been reported by von Gontard et al. (33). However, at least one large study in the Netherlands found no difference in psychopathology between children with primary and secondary enuresis (34). Of interest is an investigation by Van Hoecke et al. (35) that compared the results of the Child Behavior Checklist and the Disruptive Behavior Disorder Rating Scale in 154 children with enuresis and 153 controls. The results indicated that although the children with enuresis scored significantly higher on both scales, when the socioeconomic status of the children was controlled for the relationship was no longer present.

The occurrence of the enuretic episodes during sleep naturally led to a series of studies investigating the relationship between sleep states and the occurrence of enuretic events. The earliest of these studies suggested that the enuretic events occurred in "deep" sleep and led to a theory that enuretic events were dream equivalents (36). This theory was subsequently supplanted by Broughton's (37,38) view that enuresis was a disorder of arousal. This research suggested that enuretic episodes were preceded by arousal signals and originated in delta sleep. A further elaboration of this theory held that psychiatrically disturbed children with enuresis received normal arousal signals but did not respond to them, whereas those without psychiatric disturbance did not generate arousal signals (39). The largest and most convincing sleep studies indicate that enuretic episodes occur in each sleep stage in proportion to the time spent in that stage, when time of night also is considered (24,40,41). There have been three studies that suggested children with primary enuresis may be more difficult to arouse from sleep than control subjects, although the methodology is somewhat subjective with regard to defining arousability (6,42,43). Other research in this area has focused on combining sleep studies with cystometry (44), and may eventually lead to the identification of subtypes of children with enuresis (45,46).

The development of DDAVP as a treatment for enuresis (described later) has led to the observation that some children with enuresis do not have the ability to concentrate the urine they produce during the night and reduce urine volume (47). In a further investigation of this hypothesis, Rittig et al. (48) compared the circadian variation of plasma atrial natriuretic peptide (ANP) with the clearance of creatinine and the excretion of sodium and potassium. Subjects in the study consisted of 15 children with nocturnal enuresis and 11 control subjects matched for age, sex, and weight. The children with enuresis did not differ from control subjects with regard to

ANP, but during the first hours of sleep, they did manifest significantly more polyuria, natriuresis, and kaliuresis despite normal levels of ANP. The authors concluded that children with enuresis display abnormal diurnal rhythmicity in the urinary excretion of potassium and sodium that is not correlated with plasma levels of ANP. They speculated that the abnormalities in sodium and potassium may be related to abnormal tubular handling. This hypothesis has been further supported by subsequent research (49–51) that used radioimmunoassay to evaluate the circadian rhythmicity of plasma arginine vasopressin (AVP) in 55 children with enuresis and 15 control subjects. The AVP levels were measured under conditions of controlled water intake 3 times per day for 72 hours. Only 14 of the 55 children with enuresis had a significant decrease in AVP compared with control subjects. Nine of these 14 AVP-deficient children subsequently were found to be totally dry with DDAVP treatment.

The circadian rhythmicity of AVP has continued to be a focus of investigation because it theoretically could explain both the pathophysiology of enuresis and its response to DDAVP. Accordingly, researchers have been particularly interested in any differences that could be detected between DDAVP responders and nonresponders. One study has reported significant differences in morning values of AVP between normal control subjects (n = 7) and children whose enuresis responded to DDAVP (n = 6), as well as between the responders (n = 6) and nonresponders to DDAVP (n = 5). Thus, the morning AVP levels were able to differentiate the children with enuresis from the control subjects, and the responders from the nonresponders (52). However, further complicating this line of research has been the finding that AVP is secreted in a “pulsatile pattern,” requiring frequent sampling of plasma levels to be meaningful (53). Studies using frequent measurements of AVP have produced mixed results. Two studies that used more frequent AVP measurements (53,54) found no differences between responders and nonresponders to DDAVP. Aikawa et al. (55,56) addressed this question in a series of studies that measured AVP secretion on an hourly basis for 24 hours. The first set of these studies looked at AVP secretion profiles in children with enuresis (n = 9) and control subjects (n = 8). The results did establish that the plasma AVP level was significantly lower in the children with enuresis in the 11 PM to 4 AM time period. They then looked at the secretion dynamics in two phenomenologic subgroups of children with enuresis: those with low urinary osmotic pressure and large nocturnal urine output, as opposed to a group with normal urinary osmotic pressure and small nocturnal urine output. The results showed that the mean nocturnal AVP levels were significantly lower in the first (large nocturnal output) group and that treatment with DDAVP did produce a significant increase in AVP for this group as a whole, but not for every child.

The effect of fluid restriction on AVP levels and urine osmolality also has been investigated. These studies indicate that AVP levels are increased in both control

subjects and in children with enuresis in response to fluid restriction, and that the degree of AVP secretion is related to plasma osmolality (57). When DDAVP responders and nonresponders are compared with control subjects, all three groups manifest an increase in AVP, but the DDAVP responders showed a smaller increase than the other groups (58). Studies involving adolescents and adults with refractory enuresis also have suggested that the primary pathophysiologic mechanism may be an abnormal tubular processing of sodium related to a relative insensitivity to AVP (59,60) that is corrected to some degree by DDAVP. Similar research in children led Eggert and Kuhn (61) to hypothesize that the primary difference between children with enuresis and control subjects may be at the distal tubular AVP receptor level.

One of the newest areas of research has been the exploration of genetic linkages. It has long been known that enuresis tends to run in families, and that a positive family history can be related to positive treatment outcome (62). In general, genetic studies involve large numbers of families with multigenerational transmission of primary nocturnal enuresis. The chromosomes that have been identified to date include 13q, 12q, 8, and 22 (63–65). In some families, an autosomal dominant mode of transmission with penetrance above 90% has been identified (66).

Loeys et al. (67) studied 32 families with extensive histories of nocturnal enuresis, which ranged from two to four generations. Linkage to an area on chromosome 22q11 was noted in nine families, to 13q13–14 in six, and to 12q in four. Evidence of linkage to chromosome 8q could not be established. Thus, the findings were heterogeneous with regard to the chromosome sites involved. A genetic investigation of a large, four-generation family with a history of both nocturnal and diurnal enuresis indicated an autosomal dominant pattern with high penetrance. The author concluded that, “The most likely genetical model in this kindred seems to be a gene located on chromosome 4p16.1 causing primary nocturnal enuresis.” However, involvement of chromosome 12q24.3 could not be excluded (68).

The results of this line of research to date would support the view of von Gontard et al. (66) that “Nocturnal enuresis is a common, genetic, and heterogeneous disorder. The association between genotype and phenotype are complex and are susceptible to environmental influences.”

Laboratory Studies

The fact that urinary tract infections can precipitate enuretic events in children means that a urinalysis should be performed to rule out this readily treatable cause of enuresis.

The use of more invasive and painful studies remains controversial. Although it is certainly possible that altered bladder physiology may lead to primary enuresis, the yield from these studies does not appear to be of sufficient magnitude to warrant

subjecting all children with enuresis to them. A thorough review of this subject by Cohen (69) found the incidence of obstructive lesions in children with enuresis to be 3.7% in a primary care pediatric setting. Accordingly, he suggested that, "contrast studies are indicated only when there is significant evidence of anatomical or functional pathology by history or exam." Subsequent studies have supported this general position (23,24), while suggesting that those children with daytime wetting and overt symptoms of voiding disturbance are more apt to have urinary tract abnormalities than those who wet solely at night (70). As discussed above, ultrasound bladder measurements may prove useful in the future, but currently this is viewed as a technique utilized in research only (25).

Differential Diagnosis

The differential diagnosis includes the possibility of urinary tract infection and altered bladder physiology. There are scattered case reports of enuresis being secondary to other primary medical problems, such as hyperthyroidism (71), constipation (72), and central hormonal abnormalities (73). Although such reports are infrequent, the clinician should do a thorough physical examination and consider the possibility of underlying organic illness—particularly readily treatable constipation. Brooks and Topol (74) have reported an association between obstructive sleep apnea in children and nocturnal enuresis. They hypothesize that this could be related to the effects of sleep apnea on arousal patterns, and bladder dynamics on urinary hormone production.

There are reports of nocturnal enuresis occurring as a side effect of treatment with selective serotonin reuptake inhibitor antidepressants (SSRIs). Given the frequency with which these agents are prescribed to children, this should be considered. The chronologic correlation between the initiation of treatment with an SSRI and the onset of enuretic episodes would tend to substantiate the diagnosis (75–78). This side effect has also been reported with risperidone (79). Psychological testing in conjunction with structured interviews may provide further insight into the coexistence of psychopathology. However, the studies reviewed previously suggest that any coexisting psychological disorder should be viewed as an accompanying finding rather than as a causal effect.

The distinction between primary and secondary enuresis can be made by history.

Treatment

Although psychotherapy may be helpful for managing the behavioral disorders that accompany enuresis, it appears to have little effect on primary enuresis itself, with studies showing a success rate of 20%, which may largely be accounted for by spontaneous remission (69). Psychotherapy may be more useful for those children

with secondary enuresis, especially those whose episodes begin after a traumatic event or parental divorce, or in those cases where a specific parent–child conflict appears to be contributing to the continuation of the enuresis (Table 5.12.1) (80).

It has been shown that having nocturnal enuresis has a negative impact on self-esteem, which can be normalized by effective treatment (81–83). The factors related to negative self-image were male gender, primary enuresis, and a greater frequency of wet nights.

The two primary means of treating children with enuresis fall into the categories of behavioral and psychopharmacologic methods.

Behavioral Methods

Behavioral treatment should be attempted first because it is usually more innocuous than pharmacologic intervention. The underlying assumption of the behavioral strategy is that it is helping children with enuresis and their families master an affliction rather than tacitly implying that the children are either consciously or unconsciously causing the wetting themselves. One unfortunate consequence of various reward–punishment strategies is that they can subtly imply to children and their families that the disorder is quasi-volitional. The bell and pad method of conditioning is a reasonable first approach. A review of this treatment modality indicated that it was first reported in 1904 and has been in routine use since the 1930s (84). In reviewing the results of several studies involving over 1,000 children, Werry (85) found a success rate of 75%, and subsequent studies have been consistent with this (86). Glazener et al. (87) noted that approximately two-thirds of children treated with the alarm achieved nocturnal continence during treatment and nearly half who complete this form of treatment remained dry after the termination of treatment. In a similar study, Butler and Gasson (88) reviewed 38 studies involving at least 10 children, and found that the success rate ranged from 30% to 87%. However, there were considerable methodologic differences, including the definition of success. When they narrowed the review to 20 relatively homogeneous studies, they found an overall 65% success rate and a relapse rate of 42%. There appear to be two subgroups of responders: those who sleep through the night after treatment without wetting, and those who wake up spontaneously to go to the bathroom (89). A psychiatric disorder in the child and family stress appear to be negative prognostic factors when predicting outcome with this modality (86).

TABLE 5.12.1

FACTORS TO CONSIDER WHEN CONSTRUCTING A TREATMENT ALGORITHM FOR PRIMARY NOCTURNAL ENURESIS

Age of child
Medical cause has been ruled out
Rate of spontaneous remission (approximately 14–16% per year)

Behavioral conditioning with bell and pad or similar methodology
- Equally effective as pharmacologic treatment
- Lower rate of relapse than with pharmacologic treatment
- Safer than pharmacologic treatment

Most commonly used pharmacologic intervention is desmopressin acetate (DDAVP)
Most serious side effect (rare) is hyponatremia, leading to seizures
Imipramine is no longer first-line choice for pharmacologic treatment, but can be used for refractory individuals
Combination of behavioral and pharmacologic treatment can be considered for refractory enuresis

Butler and Robinson (90) found low functional bladder capacity and inability to be aroused by the alarm to correlate with lack of success, and a higher pretreatment frequency of enuretic events has been found to correlate with increased success with this form of treatment (91,92).

Bladder capacity also has been investigated with regard to changes occurring during treatment. Oredsson and Jorgensen (93) measured bladder capacity in 18 children with severe nocturnal enuresis before beginning a 6-week period of treatment with the bell and pad and again after treatment. Ten of the 18 children ceased wetting, but overall, there was a significant increase in bladder capacity for the entire group that did not correlate with outcome. Subsequent investigations have also reported an increase in bladder capacity following treatment with the alarm method (94,95). This may explain why one study found that children whose nocturnal enuresis responded to the alarm also had significant improvement in daytime wetting (96). Behavioral treatment continues to evolve. In a study involving 125 children, an attempt was made to replace the bell and pad mechanism with a simple alarm clock that was either set to go off at a time when the bladder might be expected to be reaching maximal capacity (group I) or after 2 to 3 hours of sleep (group II). The results were comparable with previously published figures for the bell and pad, with success noted in 77.1% of group I and 61.8% of group II, and respective 6-month relapse rates of 24.1% and 14.7% (97).

Another innovation involves replacing the pad that signals the enuretic event with a small ultrasonic monitor mounted to an elastic abdominal belt that signals the alarm when bladder capacity is reaching a predetermined threshold (98). Results of a clinical trial of this methodology were comparable with those obtained with the traditional bell and pad technique, and increases in nighttime bladder capacity also were noted (99).

An approach using bladder biofeedback has been developed for children with enuresis who are refractory to other forms of treatment, have small bladder capacities, and have evidence of an unstable detrusor (100). A subsequent report by the same group (101) also reported an increase in bladder capacity with biofeedback treatment. As noted earlier, the presence of behavioral or family functioning problems can have a negative impact on the outcome of behavioral treatment. A successful intervention in refractory children with severe wetting who have these issues has been to combine traditional alarm therapy with treatment with DDAVP

(102,103).

Glazener and Evans (104) performed a review of studies involving simple behavioral interventions for enuresis. The procedures involved included reward systems, such as star charts, nighttime awakening to urinate, retention-control training, and fluid restriction. They noted that many of the studies were small and poorly controlled, which precluded a meta-analysis. There was some suggestion that star charts and nighttime awakening achieved better outcome than no treatment. A similar review was completed for the more complex behavioral and educational interventions of dry bed training and full-spectrum home training (105). Again, there were methodologic issues that compromised many of the studies. These modalities were found to be superior to no treatment, but as stand-alone treatments were not as effective as alarm treatment. However, there was some indication that combining dry bed treatment with the alarm might provide better results than the alarm alone in some children. Bennett (106) has developed a protocol that utilizes educational and simple behavioral interventions as a prelude to treatment with the bell and pad. He reports a success rate of 85%, and a relapse rate of 15% (many of whom become dry with a repeat of the program) with this methodology. Bennett's book also contains a very useful chapter that describes the advantages and disadvantages of each of the various subtypes of the bell and pad form of treatment that are commercially available.

Psychopharmacologic Methods

The Australian psychiatrist MacLean (107) first described the efficacy of imipramine for nocturnal enuresis in 1960. Since then, there have been over 40 double-blind studies confirming the efficacy of imipramine for nocturnal enuresis. Lack of response to imipramine often can be traced to the reluctance of primary care physicians to exceed dosages of 25 to 50 mg. Nevertheless, it is reasonable to begin at a dose of 25 mg and to titrate up slowly because some children respond to the lower dosages. Allowing 4 to 7 days between dosage increments makes it possible to detect these low-dose responders. Most children respond in the 75- to 125-mg range. The upper range of dosage is determined by the child's weight, with the standard upper limit being 5 mg/kg/d. A baseline electrocardiogram should be obtained before instituting treatment with imipramine, and monitoring is advised above 3.5 mg/kg (24).

The relatively high rate of spontaneous remission in enuresis mitigates against keeping children on medication for long periods. A practical approach is to taper slowly and discontinue the imipramine every 3 months. If wetting resumes as the dosage is tapered or after it is discontinued, then the dosage can simply be titrated back up to the effective dose for another 3-month period.

There have been tragic reports of children who reasoned that if three pills would

stop the wetting for a night, then taking the whole bottle should stop it permanently. Thus, it is important to warn parents about the magical thinking of children in this regard and the importance of controlling the medication. Younger siblings also are at risk of overdosing with the medication if it is not controlled. In cases of mild-to-moderate overdose, supportive measures, including the symptomatic management of seizures and cardiac arrhythmias, may be sufficient.

There have been five studies investigating the relationship between blood level of imipramine and clinical response. One study found no correlation between improvement in enuresis and the blood level of imipramine either alone or in conjunction with its metabolites (108). However, three studies have now demonstrated a significant correlation between the diminution of enuretic events and the steady-state concentrations of imipramine plus its metabolite desipramine (109–112). One of these studies found an optimal effect when the combined steady-state imipramine plus desipramine concentrations were above 60 ng/mL (111), and another reported favorable outcomes when steady-state combined levels were greater than 80 ng/mL (109). An investigation into the role of dosage response (113) evaluated the blood level–efficacy equation in 18 children who, after baseline and placebo, received increasing dosages of imipramine at 2-week intervals. The specific dosages used were 1, 1.5, 2, and 2.5 mg/kg/d. They found that efficacy was “moderately but significantly” related to increasing dose. However, there was wide variation (sevenfold) in serum levels between the individual children at every dosage level. There is a good correlation between side effects and blood level, especially dry mouth (122). This may prove clinically useful in monitoring children who are phobic about having their blood drawn. As might be expected, the advent of treatment with DDAVP has led to a marked decline in new research concerning imipramine.

Gepertz and Neveus (114) utilized imipramine in the treatment of 49 children who had been refractory to treatment with DDAVP, the alarm, and anticholinergic treatment. They reported that 31 children (64.6%) achieved a 50% reduction in the frequency of enuresis and 22 of these realized complete cessation of the enuresis. It was also noted that seven children with comorbid attention deficit showed improvement in those symptoms as well. Thus, the authors concluded that it was reasonable to consider imipramine for children who had not responded well to other modalities.

Despite the efficacy of behavioral interventions, survey studies tend to indicate that in clinical practice medication is more apt to be used than behavioral interventions (115). A large population-based study found that only 38% of children with enuresis had seen a physician. Over one-third of this physician-treated group had been prescribed some form of pharmacotherapy, and only 3% had been advised to use the bell and pad conditioning technique (116). This may be changing, as a subsequent study reported 80% of physicians recommended the bell and pad (117).

Boulis and Long (118) have reported that family practitioners are more likely to recommend DDAVP as a first treatment for enuresis than are pediatricians.

The newest research into pharmacotherapy for enuresis involves the use of DDAVP. Moffatt et al. (119) reviewed all of the then-existing controlled studies concerning the use of DDAVP for enuresis. In the process, they located 18 randomized controlled trials (11 crossover and 7 parallel), which included a total of 689 subjects, most of whom had been refractory to prior treatment. The decreased frequency of enuretic events in the study ranged from 10% to 91%. In general, wetting resumes once the medication is discontinued. Those studies that reported long-term follow-up indicated that 5.7% remained dry after stopping the medication. The most common side effects were nasal stuffiness, headache, epistaxis, and mild abdominal pain. Positive prognostic factors appear to be fewer initial (pretreatment) wet nights and age greater than 9 years. Hogg and Husmann (62) and Terho (120) particularly looked at the efficacy of DDVAP for children who had been refractory to conditioning treatment and imipramine, using a randomized, double-blind, placebo-controlled crossover study. Of the 52 children studied (age range 5 to 13 years), 53% had a complete cessation of wetting, 19% were partial responders, and 28% had no or minimal response. The dosages used ranged from 20 to 40 μg (intranasal) and response did not persist after termination of treatment. In a 5-year retrospective review of 59 children, Key et al. (121) suggested that lower doses may be just as effective. In their series, 5 μg at bedtime was the initial starting dose, and 81% improved on less than 10 μg.

A study investigating the differential response of children with enuresis to DDAVP and the bell and pad method of conditioning found that 70% improved with the DDAVP and 86% improved with the alarm method, yielding no significant differences (122). A similar experiment that compared the therapeutic benefits of DDAVP in combination with the bell and pad to placebo found that the combination of DDAVP and the alarm resulted in significantly more dry nights (123). Leebeek-Groenewegen et al. (124) found that the combination of the alarm with DDAVP provided a more rapid response than monotherapy with the alarm, but the long-term success rates were comparable. However, Naitoh et al. (125) found that neither combination treatment with the alarm and imipramine nor the alarm and DDAVP were superior to the alarm alone. There have been reports of hyponatremia (126) and hyponatremic seizures (127–129) with intranasal use of DDAVP. A case report and literature review documented 14 cases in the English language literature with symptomatic hyponatremia involving seizures or mental status changes (130). A similar review noted that excess fluid intake was identified in 6 of 11 case reports, leading the authors to recommend that patients receiving DDAVP for nocturnal enuresis should not ingest more than 8 ounces of fluid on the nights when DDAVP is administered (131). The most comprehensive review of this subject identified a total of 93 instances of symptomatic hyponatremia in children treated with DDAVP (132).

Younger children appeared to be more susceptible and the risk was greater at the beginning stages of treatment. This increasing literature, which included some fatalities, led the U.S. Food and Drug Administration (FDA) to warn clinicians that the intranasal form of DDAVP for the treatment of primary nocturnal enuresis should be discontinued. In addition, the warning indicated that the treatment with the oral form should be discontinued during acute illnesses that might disrupt the fluid/electrolyte balance.

The formulation of oral DDAVP has made it significantly easier and safer to administer (133,134). In an early open 6-week trial involving 33 children with primary nocturnal enuresis, 5 children responded to 200 μg/d and 17 to 400 μg/d, whereas 7 showed no response, and 4 dropped out. A multicenter, randomized study compared 200- and 400-μg doses of the oral preparation, as well as a 20-μg dose of the spray. No significant differences were found between any of the treatment conditions. However, there tended to be fewer wet nights when the children who initially received 200 μg of the oral preparation were increased to 400 μg (135). Similar positive results with oral DDAVP have been reported by Schulman et al. (136).

The dose response of oral DDAVP was explored in a randomized, placebo-controlled study that used 200-, 400-, and 600-μg daily doses. The 400- and 600-μg doses were significantly more effective than placebo, and there also was a significant linear trend for decreases in wet nights with increasing dosage (137).

An early oral DDAVP study with adolescents (138) has also provided long-term follow-up data (139). The initial study included two 12-week treatment periods with most of the patients receiving 400 μg/d. The initial studies showed that oral DDAVP was significantly more effective than placebo. The long-term, 7-year follow-up indicated that the "cure rate" at both the 2-year and 7-year follow-ups was greater than would be expected by data on the rate of spontaneous remission.

A large Canadian study found that long-term administration of oral DDAVP was safe and well tolerated (140). Consistent findings related to predictors of successful treatment are older age, larger bladder capacity, and fewer pretreatment numbers of wet nights (141–147).

Outcome and Follow-up

The natural history of primary enuresis must be taken into account in any treatment plan, whether it is primarily behavioral or pharmacologic. There is a high rate of spontaneous remission between the ages of 5 and 7 and again after the age of 12 years. Accordingly, the clinician might want to wait until after the age 7 of years before instituting pharmacologic treatment, unless other factors indicate otherwise. Similarly, the strong possibility of spontaneous remission should be considered in any positive treatment response after 10 or 11 years of age. In general, the rate of

spontaneous remission from year to year is in the range of 14% to 16% (89,112). There has been one large follow-up study that compared observation, imipramine, DDAVP, and the alarm system. Patients were weaned from therapy after 6 months. Continence was assessed at the 3-, 6-, 9-, and 12-month points of the protocol, so that the 12-month assessment would be 6 months after treatment ceased. Among the observation group (*n* = 50), only 6% were continent at 6 months and 16% at 12 months. Of the imipramine group (*n* = 44), 36% were continent at 6 months while still on medication, but this decreased to 16% at the 12-month assessment. The corresponding figures for DDAVP (*n* = 88) were 68% continent at 6 months, but only 10% at 12 months. The alarm system showed the best long-term effects, with 63% continent at 6 months, and 56% at 12 months (148). A systematic review of the literature with regard to treatment with the alarm, imipramine, and DDAVP indicated that there is less risk of relapse with the alarm (149). The data with regard to treatment outcomes clearly indicate that behavioral interventions should constitute the first line of treatment, as they do not possess the side-effect potential of pharmacologic interventions (150). The bell and pad method of conditioning is the most thoroughly researched form of behavioral treatment. The relapse rate after termination of this treatment is also substantially less than that seen with either DDAVP or imipramine. For children who do not respond to the bell and pad, treatment with DDAVP is a reasonable alternative. Treatment with imipramine is now usually reserved for children who have been refractory to other interventions.

Following the introduction of DDAVP, there were significant cost differentials related to the different forms of treatment, as treatment with DDAVP was significantly more expensive than treatment with either the bell and pad or imipramine (151). However, DDAVP is now available in generic form, so the large cost differentials no longer exist.

Areas for Future Research

As indicated by the new research reviewed previously, there has been a dramatic increase in research into the etiology and treatment of enuresis. Much of this has been stimulated by the recognition that DDAVP is an effective treatment for the disorder. Despite this new research, a definitive explanation that would link DDAVP efficacy with the pathophysiology of the disorder has yet to be proven, and there is no consistently reliable way to differentiate DDAVP responders from nonresponders, either retrospectively or prospectively.

This and other findings related to bladder physiology and anatomy suggest that we might ultimately be able to differentiate distinct phenomenologic subgroups that relate to treatment outcome. Of particular interest in this regard are the studies involving changes in bladder capacity that result from treatment and correlate with outcome.

The longstanding observation that enuresis has a hereditary basis has been advanced by the elucidation of genetic linkages in some large, multigenerational pedigrees. This research will likely continue to advance and, when coupled with physiologic variables that predispose to enuresis, may ultimately provide important information on clinical subtypes. Thus, while it appears increasingly likely that a single etiology for all children with enuresis will not be identified, it may be possible to identify clinically relevant subtypes.

ENCOPRESIS

Definition

Encopresis is defined by DSM-5 (American Psychiatric Association, 2013) as the "repeated passage of feces into inappropriate places." There is a notation that the soiling is usually involuntary, but may be intentional in some cases. The manual goes on to note that the soiling must occur at least once a month for at least 3 months and that the mental or chronologic age of the child must be at least 4 years. Physical disorders must, of course, be ruled out. If there has been a period of fecal continence preceding the recurrence of soiling, it is classified as secondary encopresis.

The DSM-5 also denotes two subtypes of encopresis, which it labels as "with constipation and overflow incontinence" and "without constipation and overflow incontinence." The former category roughly corresponds to what has been referred to in the literature as retentive encopresis, whereas the latter corresponds to what has been known as nonretentive encopresis.

Prevalence and Epidemiology

A study involving 8,863 children found a prevalence of 1.5% among children between 7 and 8 years of age, with a male-to-female ratio of over 3:1 (152). In the Isle of Wight Study, Rutter and colleagues (2) found that 1.3% of boys between the ages of 10 and 12 years soiled at least once a month, with the corresponding figure for girls being 0.3%. That study also found a significant relationship between enuresis and encopresis (153). A more recent, large population-based study in the Netherlands investigated the prevalence in a sample of 13,111 5- to 6-year-old children, and 9,780 11- to 12-year-old children. The authors report a prevalence of 4.1% in the 5- to 6- year age group. The corresponding frequency for the older age (11 to 12 years) group was 1.6%. Of interest is the finding that 37.7% of the younger age group children and 27.4% of the older age group had not been taken to a physician for evaluation (154). A large population-based questionnaire study reported episodes of fecal incontinence in 9.8% of first-graders, and 5.6% of fourth-graders (8). Of interest was a positive correlation between daytime urinary

incontinence and fecal soiling.

Clinical Description

Encopresis has been classified in different ways. As noted, DSM-5 made a distinction between primary and secondary encopresis and has added subtypes that denote the distinction between retentive and nonretentive encopresis. Retentive encopresis is characterized by a cycle of several days of retention, a painful expulsion, and another period of retention. While the fecal mass is growing, there may be leakage around the mass. The category of nonretentive encopresis applies to those children who simply do not control the expulsion of feces on a psychological, physiologic, or combined basis.

Hersov (155) has proposed three categories: (a) children who have adequate bowel control and volitionally deposit feces in inappropriate places; (b) children who either are unaware that they are soiling or are aware but unable to control the process; and (c) situations where the soiling is due to excessive fluid, which may be caused by diarrhea, anxiety, or the retentive overflow process described previously. The last mechanism is responsible for approximately 75% of this category.

The importance of constipation to the development of retentive encopresis has led to the formulation of proposed criteria for functional fecal retention (FFR), which include a history greater than 12 weeks with passage of large diameter stools that are sufficiently large to obstruct the toilet, abdominal pain that is relieved by laxatives or enemas, and fecal soiling (156).

Etiology and Pathogenesis

There have been extensive investigations into the physiologic basis for encopresis. Loening-Baucke (157) found that 56% of children with retentive encopresis were unable to defecate rectal balloons, and most of these children had abnormal contractions of the external anal sphincter. This study also had prognostic significance in that only 14% of those who were unable to defecate the rectal balloons had responded to treatment after 1 year, whereas 64% of those who could defecate the balloons recovered after 1 year. Similarly, only 13% of patients who were unable to relax the anal sphincter at initial evaluation were improved 1 year later, whereas the corresponding figure for those who could relax the sphincter was 70%. Interestingly, none of the patients who presented with an abdominal fecal mass at the time of the initial evaluation showed improvement 1 year later, regardless of the ability to defecate the rectal balloons. Constipated children subsequently were compared with control subjects on a wide range of physiologic measures during the act of bearing down (158). These studies revealed that the act of bearing down led to decreased anal sphincter activity in 100% of control children, 58% of constipated

children who were able to defecate a rectal balloon, and 7% of those constipated children who were unable to defecate the balloon. The latter group was significantly less likely to respond to conventional laxative treatment, and the authors concluded that the increased external sphincter activity could relate to their chronic fecal retention and encopresis. A companion study (159) investigated the social competence and behavioral profiles of 38 children with encopresis and correlated physiologic variables of anorectal manometric and electromyographic evaluations to treatment outcome. The study found that social competence and behavioral rating scores were not significantly different between those boys who were or were not able to defecate the balloons. The behavioral problem ratings also were similar in both physiologic subgroups of girls. The social competence score of the girls who could not defecate the balloons was lower than that of those who could. The follow-up data indicated that the behavioral and social competence scores did not correlate with successful outcome at 6-month and 1-year follow-ups, but there was a significant negative correlation between positive outcome in the inability to defecate the balloon and the inability to relax the sphincter. Thus, the physiologic variables were predictive of outcome, and the psychological variables were not. A subsequent study by the same group with a similar design continued to demonstrate some predictive value of the balloon test, in that children with functional constipation and encopresis who were able to defecate the balloon were twice as likely to have recovered at 12-month follow-up. However, the author concluded that even though these results were statistically significant, the calculation of predictive value indicated that the defecation test could not, in and of itself, reliably predict recovery (160).

A similar study at a different center concluded that a significant number of boys with encopresis have abnormalities of anorectal expulsion dynamics, but the researchers could not find abnormalities of anorectal sensory or motor function (161,162). They specifically investigated pudendal nerve terminal motor latency in 23 children with encopresis, compared with 23 control subjects, and could find no significant difference. However, anal electromyography did indicate nonrelaxation of the external anal sphincter in 75% of the encopretic children, as opposed to 13% of the control subjects, as well as lower pressures at rest and with squeezing. Complementary abnormalities of anal sphincter function have been reported by others (163,164).

Another approach has been to investigate potential involvement of hormones that affect gastrointestinal motility. Stern et al. (165) measured plasma levels of gastrin, pancreatic polypeptide, cholecystokinin, motilin, thyroxin, estrogen, and insulin at several intervals after the administration of a standardized meal to 10 children with encopresis and the same number of matched control subjects. The authors reported significant differences for postprandial levels of pancreatic polypeptide, which peaked earlier and remained higher in children with encopresis, as well as a lower

motilin response. However, the authors could not entirely rule out that their findings were not the result of chronic constipation, rather than the cause (165).

Environmental factors have been noted for some time and include the observations of Freud and Burlingham (166), who noted a high frequency of soiling and wetting in children separated from their parents during World War II.

At least three studies that revealed no correlation between social class and soiling (153,167,168) specifically looked at associated psychopathology in boys with primary encopresis, compared with those with secondary encopresis. They found that the children with primary encopresis were more likely to have experienced developmental delays and to have associated enuresis, whereas those with secondary encopresis had experienced more psychosocial stressors and had higher rates of associated conduct disorder. A study involving 86 children with encopresis and 62 control children found that children with encopresis had more symptoms of anxiety and depression, more attentional difficulties, more disruptive behavior, and poorer school performance. However, the differences only reached significant levels for a minority of the children with encopresis (169). Mellon et al. (170) have reported higher rates of fecal soiling in children who have been sexually abused.

Klages et al. (171) reported higher rates of both enuresis and encopresis in children with a prepubertal and early adolescent bipolar disorder phenotype as compared to controls. An investigation utilizing the Child Behavior Checklist identified significantly more behavioral difficulties in children with functional nonretentive fecal soiling when compared to a Dutch normative sample. Von Gontard and Hollmann (172) have reported elevated Child Behavior Checklist scores and comorbid psychiatric disorders in children who present with both enuresis and encopresis. Large epidemiologic studies have suggested higher rates of psychological disturbance in children with encopresis (173,174).

Laboratory Studies

The physiologic studies described previously must be considered research investigations and not the representation of a usual and customary workup. However, they do suggest that a more detailed physiologic investigation than usually is done may be warranted. Usually, once the more obvious physiologic problems, such as Hirschsprung disease, are ruled out, the problem is considered to be psychogenic.

The plain abdominal x-ray reveals evidence of fecal retention. In general, a positive rectal examination is sufficient to determine fecal retention, but a negative rectal examination does not rule it out, and in those cases, the abdominal x-ray can be helpful in establishing the diagnosis (175).

One of the most important investigations may well be a thorough history that documents the frequency, nature, and circumstances of the soiling events in great detail. This history should be elicited both from the parents and from the child.

Psychological testing and evaluation are important in providing a thorough picture of the child, but it remains difficult to know if concomitant psychological problems are associated, causal, or secondary.

Differential Diagnosis

The differential diagnosis of encopresis must take into account that the soiling can be either a symptom of another problem or the primary problem itself. For example, historically, encopresis and enuresis have been reported to occur under stress in normal children and to remit when the stressor is removed. Similarly, in children who have significant developmental delays, the encopresis may be only one expression of the primary problem. Children who are impulsive and hyperactive may have occasional episodes of encopresis simply because they do not attend to the stimuli until it is too late. Thus, the symptom of encopresis must be viewed in the context of the child's larger psychological and environmental profile. Strictly medical causes, such as Hirschsprung disease, stenosis of the rectum or anus, smooth muscle disease, and endocrine abnormalities, also should be ruled out.

Treatment

The most widely accepted first line of treatment is one that encompasses educational, psychological, and behavioral approaches. As outlined by Levine (176), this approach entails an initial meeting that is designed to educate both the parents and child about bowel function and to diffuse the psychological tension that may have developed in the family around the encopresis. This educational and psychological intervention is then followed by an initial bowel catharsis, after which the child receives daily doses of laxatives or mineral oil. There also is a behavioral component to the treatment, which consists of daily timed intervals on the toilet with rewards for success. A 78% success rate has been reported for this approach, without symptom substitution (177–179). The addition of a behavior management component to the intensive medical treatment provides some additional benefit (Table 5.12.2).

TABLE 5.12.2

FACTORS TO CONSIDER WHEN CONSTRUCTING A TREATMENT ALGORITHM FOR ENCOPRESIS

Subtypes of encopresis
  Retentive (most common)
  Nonretentive
  Volitional (least frequent)
A thorough history is essential that documents frequency, nature, and circumstances of event
First line of treatment for retentive subtype usually includes:
Education about bowel functioning with both parents and child

Physiologic treatment with laxatives or mineral oil
Behavioral component with time intervals on toilet and positive reinforcement
Extensive research into biofeedback
Not proven to be more effective than traditional interventions
May be a consideration in refractory cases
Case reports of imipramine in the treatment of nonretentive encopresis
Psychodynamic assessment for those with volitional encopresis

Stark et al. (180) have replicated earlier work reporting the efficacy of group treatment with an educational and behavioral focus in conjunction with medical management for children who had not responded to medical management alone.

The adjunctive use of oral laxatives and conditional rectal cathartics also has been investigated (181). Specifically, the authors compared the results obtained with children who were all treated with a high-fiber diet, initial bowel evacuation, behavior modification program, and random assignment to either oral laxatives (n = 24) or conditioning rectal cathartics (n = 37). Only 61 of 136 patients evaluated completed treatment, and thus there was a high dropout rate. No significant outcome difference was found between the two groups, and 87% continued in remission at 6- to 12-month follow-up. Nolan et al. (182) used a random allocation design to compare combined treatment with laxatives and behavior modification (n = 83) to behavior modification alone (n = 86). At 12-month follow-up, 51% of the combined therapy group had at least one 4-week period without an encopretic episode, compared with 36% of the behavior modification group. After the authors excluded children with poor compliance, there was no statistical difference between groups, although the authors maintained that from a clinical perspective, the use of laxatives combined with behavior modification was superior to behavior modification alone. Laxative therapy is an important component of treatment for children who have encopresis related to chronic constipation. A number of studies have reported success with polyethylene glycol (PEG) 3350 for this group (183–186).

Loening-Baucke (187) has expanded on the pathophysiologic studies described earlier by exploring the utility of biofeedback training in children with abnormal defecation dynamics. Specifically, patients (ages 5 to 16 years) were randomly assigned to traditional medical treatment alone (n = 19) or conventional treatment plus up to six biofeedback sessions. Eighty-six percent of the biofeedback group had learned normal defecation dynamics at the conclusion of biofeedback treatment. At 7-month follow-up, 77% of the biofeedback group had normal defecation dynamics, as opposed to only 13% of the conventionally treated. The improvement in defecation dynamics was correlated with clinical improvement at 12 months (16% with conventional treatment and 50% with biofeedback). Similar successful results were reported in a European study (188).

A longer follow-up study (4.1 ± 1.5 years) compared the long-term outcome in 129 children with constipation and encopresis, as well as abnormal defecation dynamics, who were treated with conventional treatment, with 63 children who

received additional biofeedback training that was directed toward normalizing the defecation dynamics. The results indicated that both groups showed similar rates of improvement (86% of the conventionally treated and 87% of the biofeedback group). At long-term follow-up, complete recovery was documented in 62% of the conventionally treated, 50% of those who had achieved success with the biofeedback treatment, and 23% of those who had not responded to biofeedback treatment. The length of time at follow-up was significantly related to recovery for the group as a whole, suggesting that the natural history of the disorder is to move toward continence. The author concluded that biofeedback treatment cannot be demonstrated to be statistically superior to conventional treatment (189).

A subsequent study by another group with a somewhat similar design reached the same conclusion (190), and two large literature reviews also failed to demonstrate any benefit from biofeedback as compared to the standard medical treatment (191,192). However, research into biofeedback treatment continues using a newly developed portable apparatus (193), and as an adjunctive treatment in combination with other behavioral strategies and laxative therapy (194,195), have reported a significant decrease in soiling frequency and laxative use in a group of 36 patients treated with biofeedback who had a history of constipation and encopresis, and who had not responded to 6 months of conventional treatment.

Pharmacologic treatment with imipramine also has been reported as useful for encopresis. There have been 15 reported cases of children with encopresis responding to imipramine, which have been described in six papers (196–201). All but three of the reported subjects are male. In general, the therapeutic effect occurred within a few days to 2 weeks. The doses of imipramine reported are relatively low, in the 25- to 75-mg range. There also is a similar positive case report involving amitriptyline treatment of a 6 year old (202). There is one double-blind study demonstrating the effectiveness of the prokinetic agent cisapride (Propulside) for encopresis related to constipation (203). However, this agent has been removed from the market in the United States by the FDA, due to serious side effects.

Outcome and Follow-up Data

The 78% success rate described by Levine suggests that most children will respond to a relatively innocuous approach that involves educational, behavioral, and physiologic components, as do the follow-up data of Loening-Baucke (189). In general, the longer-term follow-up studies consistently indicate that the passage of time is an important contributor to remission of the disorder (189,204). The epidemiologic data also indicate that the effects of maturation will provide a significant number of spontaneous remissions from year to year. The evaluation of any long-term intervention such as psychotherapy should take this factor into account. All but a few children will have either responded to treatment or spontaneously

remitted by age 16 years, and persistence beyond that age is quite unusual (205).

Areas for Future Research

This review suggests that encopresis is an excellent paradigm for assessing the relative impacts of biologic, psychological, and social factors. For example, do the physiologic findings described previously represent a constitutional vulnerability, or are they the result of the effects of chronic constipation on the bowel? The symptom of encopresis in its various presentations can be a fruitful area of research for those interested in elucidating the interrelation of mind, body, and culture in children.

APPENDIX: ANTIENURETIC AGENTS

Desmopressin, Oxybutynin, and Tolterodine

Table 5.12.3 depicts the pharmacologic characteristics of medications used for enuresis. Desmopressin (DDAVP) is a synthetic antidiuretic hormone (ADH), a powerful inhibitor of the production of urine. It can be administered orally or via intranasal spray. One review suggested that desmopressin helps approximately 25% of children who use it, with minimal risk of adverse effects. Although desmopressin is usually well tolerated, the beneficial effects often do not endure over time. The most effective treatment for enuresis is the use of behavioral interventions, such as a "pad and buzzer" or a "moisture alarm." However, DDAVP can be a useful short-term adjunct, as in the facilitation of sleepovers or overnight camp stays. For longer-term pharmacologic management of enuresis, usually in cases unresponsive or only partially responsive to behavioral interventions, antimuscarinic agents can occasionally be useful. Alternatives to the time-tested use of low (25 to 50 mg hs) or regular dose imipramine include oxybutynin (Ditropan) or the less sedating tolterodine (Detrol). As is the case of other pharmacologic interventions for enuresis, beneficial effects usually disappear rapidly upon drug discontinuation (Table 5.12.3).

TABLE 5.12.3

CLINICAL GUIDANCE ON ANTIENURETIC AGENTS USED IN PEDIATRIC PRACTICE

Drug	Mechanism of Action	Main Indications and Clinical Uses	Dosage (mg/day)	Schedule	Adverse Effects
Desmopressin[a]	Antidiuretic hormone analog	Enuresis	0.1–0.6	qhs/bid	Headache Nausea Hyponatremia and water intoxication at toxic doses

Oxybutynin	Antimuscarinic agents	5.0–15	bid/tid	Anticholinergic side effects
Tolterodine		1–2	bid	Less anticholinergic effects, less sedation

[a]Can be useful for acute situations (e.g., sleepaways).

ACKNOWLEDGMENT

The author wishes to thank Ms. Patsy Kuropatkin for her invaluable assistance in the preparation of this manuscript.

5.13 PERSONALITY DISORDERS

CHAPTER 5.13 ■ PERSONALITY DISORDERS IN CHILDREN AND ADOLESCENTS: A FOCUS ON BORDERLINE PERSONALITY DISORDER

EFRAIN BLEIBERG AND CARLA SHARP

The study of personality disorders (PD) is fraught with more controversies than any other area of psychopathology, as Millon and Davis noted. The controversies have been particularly pronounced regarding the child and adolescent antecedents of the PD of adulthood. Until recently, there has been considerable reluctance to diagnose PD in children and adolescents, a reluctance that is still present among many mental health professions (1,2).

Such reluctance is based on concerns about stigma—a significant issue particularly in regard to diagnosis such as psychopathy, and antisocial, borderline, or narcissistic personality disorder (3), which evoke rather intense negative responses in others, including mental health professionals, the difficulty of distinguishing the "normal" turmoil of adolescence from PD; and the incompleteness and fluidity of children and adolescent's development. This fluidity accounts for constant chances in every aspect of children and adolescent's bodies and personalities, which in turn, affects their self-image and their patterns of coping, thinking, feeling, and relating.

This chapter will focus on borderline personality disorder (BPD) in adolescence, which has been the subject of the largest body of empirical investigation among the PD in children and adolescents over the last two decades. BPD is illustrative of the processes by which biologic and psychosocial risk and protective factors interact to shape, organize, and reinforce the developmental trajectories leading to the PD that emerge in adolescence. This review will seek to establish whether there is sufficient data to justify a valid and reliable diagnosis of BPD in adolescence with a definable clinical presentation, developmental trajectory, course and outcome, including continuities and discontinuities between adolescent and adult BPD. Furthermore, this chapter also examines the literature on evidence-based psychosocial and biologic treatment, including promising treatment currently under development or undergoing testing of effectiveness.

DEFINITION AND PHENOMENOLOGY OF BORDERLINE PERSONALITY DISORDERS IN ADOLESCENCE

DSM-5 (4) section II lists nine criteria, of which at least five must be present to qualify for a diagnosis of BPD. These are:

1. A pattern of unstable intense relationships
2. Inappropriate, intense anger

3. Frantic efforts to avoid abandonment affective instability
4. Affective instability
5. Impulsive actions
6. Recurrent self-harm and suicidality
7. Chronic feelings of emptiness or boredom (dysphoria)
8. Transient, stress-related paranoid thoughts
9. Identity disturbance and severe dissociative symptoms

DSM-5 includes also a section III that indicates that more research is needed to validate a model of PD that is not based on categorical symptoms (3), but on impairments in self and interpersonal function (criterion A) and pathologic personality traits (criterion B). This alternative model of diagnosing PD reflects a growing consensus that PD should be understood as *dimensional* disorders in which individuals present varying degrees of pathologic personality traits that impair functioning.

This dimensional model of PD is consistent with the model proposed in this chapter. The aspects of impairment proposed in DSM-5's alternative model are particularly relevant to this chapter's proposed description of core dysfunctions in adolescent BPD.

They include:

1. *Identity:* Referring to the degree of difficulty experiencing the self as a distinct and coherent entity with a sense of continuity over time.
2. *Self-direction:* Involving the extent of impairment in experiencing oneself as an *agent*, the originator and "owner" of one's behavior, capable of setting and pursuing short- and long-term goals.
3. *Empathy:* Describing the extent of impairment in the capacity to understand the experience and intentions of others, appreciate and tolerate other people's perspective, and understand the impact one has on others and others have on us.
4. *Intimacy:* Assessing the impairment in the capacity for closeness, trust, and reciprocity in relations.

These impairments are highly consistent with an emerging consensus (5) that the core dimensional impairments characterizing BPD are *affective dysregulation, impulsivity,* pervasive *social dysfunction,* and *impairments in identity.*

Despite long-standing agreement that PD, in general, and BPD, in particular, are rooted in childhood and adolescent—and that youngsters are unlikely to wake up after their 18th birthday to discover that they have become borderline overnight—there is much debate about the validity and stability of the BPD diagnosis in adolescence over time.

Two decades of research (6–9), however, provide evidence that the reliability and validity of the BPD diagnosis in mid-to-late adolescence are comparable to that of adults.

DSM-5 provides criteria for BPD unmodified by developmental considerations

but suggests that BPD—as well as other PD—can be diagnosed in children and adolescents when maladaptive traits have been present for at least 1 year and the traits are pervasive, persistent, and unlikely to be limited to a particular developmental stage. In both adolescent and adults, BPD is broadly defined by affect dysregulation, marked impulsivity, including self-injurious behavior, and a pervasive pattern of instability of interpersonal relationships and self-image. At a psychological level, the core features of adolescent and adult clinical presentations are high sensitivity and anxious expectation of rejection, abandonment or loss, difficulties with trust and cooperation, proneness to shame, negative perception of self and body, and explosive rage and intermittent hostility (10). Several studies (11–13), however, show relatively low stability of categorical symptoms (if a symptom present or not) as part of a polythetic criterion (e.g., a set of five of nine categorical features) for the adolescent BPD diagnosis.

Greater stability and accuracy of diagnosis can be achieved when considering the core dysfunctions of affect dysregulation, impulsivity and pervasive disturbances in interpersonal relations, and self-image in a *dimensional* approach. Diagnosing BPD with a dimensional, rather than a categorical approach is particularly relevant in adolescence, as a dimensional approach can account for the developmental variability during adolescence and in the transition to adulthood, identifying a population of adolescents with current psychopathology and psychosocial dysfunction (4); very high comorbidity with other psychiatric disorders (14) such as eating disorders, depression and anxiety disorders, and substance use disorders; and poor outcomes in longitudinal studies (15).

Differences between adolescents and adults indeed suggest a developmental trajectory of consistent and continuing impairment but with changing clinical features. Compared to adults with BPD, adolescents with BPD present with more acute and dramatic symptoms, such as self-harm and suicidality (see section on Diagnosis and Clinical Features), explosive rage, and other impulsive and self-damaging behaviors. By contrast, unstable relationships and identity disturbance are more often diagnosed in adults with BPD.

Fear and anticipation of rejection and abandonment appear to be a specific inclusion criterion in adolescents, with patients endorsing this symptom meeting full diagnostic criteria in 85% of cases (16). Westen et al. (8) conclude that feelings of emptiness, dramatic fluctuations in self-image, and dependence on the presence and responsiveness of others to maintain a sense of identity are the most distinctive features associated with the diagnosis of BPD in adolescents. These findings were confirmed in recent work utilizing modern latent trait approaches (17).

Assessing the dimensional features of personality pathology emerging in adolescence and the more pervasive and persistent dysfunctions in the core dimensions that characterize BPD in adolescents are critical in order to differentiate BPD in adolescents from the acute or episodic manifestations of other psychiatric

disorders or developmental crisis, which can occur comorbidly with BPD. Of particular note are the diagnostic entities of nonsuicidal self-injury (NSSI) and suicidal behavior disorder, which have been included in section III of DSM-5 (4). NSSI is common in adolescence and suicide attempts can be associated with a range of conditions or developmental crisis, including major depression and substance abuse. However, repetitive NSSI, in which self-harm becomes a device to achieve emotion regulation, relieve feelings of emptiness, and a response to perceived or anticipated rejection or abandonment are highly associated with BPD (18). Moreover, BPD is much more likely in adolescents who present both NSSI *and* suicide attempt than in those adolescents who present one or the other.

According to Ha et al. (19), a confluence of internalizing (mood and anxiety disorders, including obsessive-compulsive disorder (OCD), posttraumatic stress disorder (PTSD), and separation anxiety disorder) and externalizing disorders (attention-deficit hyperactivity disorder [ADHD], oppositional disorder, conduct disorder, and substance use disorders) is predictive of a BPD diagnosis. Thus, clinicians should use the presence of this complex suggestive of a BPD diagnosis.

History

Clinical descriptions of BPD in childhood, beginning in the late 1940s, formulated these children's symptoms within a psychoanalytic framework (2). Margaret Mahler et al. (20) suggested the term "borderline psychosis" to refer to children at the milder end of a proposed continuum that extended to the most severe psychotic conditions of childhood. Ekstein and Wallerstein (21) used the term "borderline" to describe children who were not mildly or incipiently psychotic but presented, instead, a stable condition, paradoxically defined by its persistent instability, and characterized by rapid and ongoing shifts in levels of ego functioning, including reality testing, relationships with others, and defense mechanisms. Such formulations defined borderline children as less severely disturbed than psychotic children but more seriously impaired than neurotic children. In a similar vein, Kernberg (22) characterized "borderline" as a level of development and organization underlying several PD. This developmental pattern, according to Kernberg, included limitations in the capacity to differentiate self from others, reliance in primitive defenses, and attainment of reality testing, without the achievement of object constancy and identity integration.

Such formulations of borderline pathology in children used diverse clinical criteria, and likely described a heterogeneous population (23), but laid the foundation for the development of formal criteria for BPD in children and adolescents.

Goldman et al. (24) were the first to adapt standardized adult DSM criteria for BPD in children and adolescents, thus allowing for the comparison of findings from different studies and the application of adult assessment tools to child and adolescent

samples.

Epidemiology

Recent reviews of epidemiologic studies suggest that the prevalence of BPD in adolescence is similar or higher than in adults, affecting 3% to almost 6% in community samples (25), 11% of those seeking outpatient services (26,27), and almost 50% of those admitted to inpatient treatment. For example, Grilo et al. (28) demonstrated similar rates of BPD in inpatient settings for adolescents (49%) and young adults (43%) using the same measures for both samples.

Etiology

Models are emerging seeking to integrate biologic and psychosocial interaction factors interacting with one other to generate, organize, and reinforce a developmental trajectory leading to the emergence of BPD in adolescence with core dimensional features of affect dysregulation, impulsivity, and a pervasive pattern of impairment in relationships and self-image (29). Existing research, as section III of DSM-5 points out, does not yet support a comprehensive developmental–etiologic interactional model of BPD. In this section, we discuss growing understanding BPD as emerging from biologic vulnerabilities interacting with specific psychosocial factors.

A selective review of investigations of genetic, biologic, and psychosocial factors in the etiology of BPD will be followed by an examination of these emerging interactional models.

Genetic Factors

Studies investigating genetic factors associated with BPD have included family, adoption, and twin studies.

Twin studies suggest that BPD features in adults have heritability between 40% and 50% (30–32). Two studies show that children aged 9 to 15 who carried the S allele of the serotonin transporter gene promoter region (5-HTTLPR) presented with the highest degree of BPD features (33). This finding is suggestive that the genetic diathesis driving the core features of BPD development is a *high sensitivity* and *reactivity to stress* and thus, a heightened sensitivity to the adequacy or inadequacy of the child's attachment context to regulate and modulate stress.

Evidence of this interaction between genetic diathesis and attachment context is provided by a large study of a birth cohort of over 1,100 families with twins. In this study, Belsky et al. (34) found that the likelihood of extreme dimensional features of BPD, assessed at age 12, more than doubled (8% vs. 3%) in children with a family

history of psychiatric disorder, as an index of genetic vulnerability. The likelihood of extreme dimensional features of BPD also more than doubled (7% vs. 3%) in children with a history of maltreatment. However, in those with *both* a genetic vulnerability *and* maltreatment, the extreme dimensional features of BPD were present in 40%.

Neurobiologic Factors

Studies of adults with BPD suggest dysfunctions in 5-HT, dopamine, monoamine oxidase, and vasopressin are likely associated with impulsivity, aggression, and self-injury in BPD. On the other hand affective dysregulation, a core dimension of BPD, may be associated with dysfunctions in the acetylcholine and noradrenaline systems (35).

Neuroimaging studies in adults with BPD identify reduced volumes of the amygdala; hippocampus, orbitofrontal cortex (OFC) and anterior cingulate cortex (ACC), brain areas that play key roles in emotion regulation and in the processing of social and social–emotional information (36). In response to affective stimuli, BPD patients show bilateral increases in activation of the amygdala, suggesting an increased reactivity to emotionally relevant stimuli (37), further supporting the notion of deficient processing of affective stimuli in BPD.

Taken together, studies of the neurobiologic correlates of BPD converge in pointing to a dysfunctional frontolimbic network that may account for both symptoms of impulsive aggression and affective dysregulation and the characteristic hyperreactivity of BPD individuals to loss, rejection of frustration.

Reduced volumes in left ACC and right orbitofrontal cortex (OFC) have been identified in adolescent patients with BPD and correlate with impulsivity and NSSI (38,39). However, contradictory findings have also been reported (40).

Diffusion tensor imaging studies show decreased fractional anisotropy in the fornix of adolescents with BPD (41). New et al. (42) report decreased fractional anisotropy in the inferior longitudinal fasciculus and other areas, which appear to be present in adolescents but not in adults with BPD.

These findings, and the overall inconsistency in neuroimaging studies of BPD on adolescence, suggest neurodevelopmental differences between adolescents and adults with BPD, that highlight that during adolescence there are increased deficits in connectivity between the medial prefrontal cortex and the orbitofrontal cortex, on the one hand, and the amygdala, hippocampus, posterior cingulate and insular cortex, on the other hand (42). These findings correlate with at least one FMRI study documenting hyperresponsiveness of the amygdala in adolescents with repetitive NSSI.

These findings are associated with the characteristic neurodevelopmental features of adolescence involving synaptogenesis (increase in the number of synaptic connections) followed by synaptic pruning and axonal myelination. The brain areas

involved in this structural reorganization are particularly the prefrontal cortex, the anterior cingulate, and the superior temporal cortex, areas that, as discussed below, are involved in social cognition, mentalizing, and social cognition–mediated ("top-down") affect regulation (43).

While this reorganization will eventually lead to more efficient brain networks and neural transmission in early adulthood, while it is taking place, it significantly impairs social cognition, mentalizing, and affect regulation in adolescence, arguably creating a critical vulnerability to the emergence of BPD in predisposed adolescents.

Psychosocial and Psychological Factors

A large body of research, including longitudinal studies, offers robust evidence that a range of adverse and traumatic childhood experiences (in particular experiences of emotional neglect and abuse and broader problems in family environment [including parental conflict, separation, and loss and parental psychopathology]) and low socioeconomic status are associated with the key features of BPD (43–46).

The children in the community study (47), for example, found that childhood maltreatment prospectively predicted a high risk for BPD in young adulthood even after controlling for other PD, parental education, and psychiatric disorders in the parents in this same study. Early separations from the mother and the family's low socioeconomic status also predicted BPD symptomatology in adolescence and were largely independent from other predictive factors such as maltreatment.

Lyons-Ruth et al. (48) identified maternal withdrawal at age 18 months as a predictor of BPD symptoms in adolescence. Carlson et al. (49) identified a strong relationship between early exposure to maltreatment and parental hostility and attachment disorganization (see section Interactional-Integrating Models), which, in turn, is prospectively predictive of BPD symptoms in middle childhood, adolescence, and adulthood.

Association between the broader psychosocial context and BPD symptomatology is suggested by Wilkinson and Pickett (50) who find a substantial correlation between countries' levels of income inequality and levels of mental health problems such as substance abuse and teen parenthood associated with BPD.

Arguably, income inequality is a marker of social cohesiveness and social reciprocity versus lack of cohesion and social exclusion.

Psychological research has illuminated the relationship between patterns of social interaction and emotional–interpersonal problems. The domains of sensitivity to social rejection and abandonment, aggression in interpersonal relationships, and difficulties forming trusting and cooperative relationship appear particularly relevant to BPD symptomatology (51).

These studies offer a bridge to integrating perspectives that focus on the interactive development of genetically prepared mechanisms to appraise and regulate self, affect and relationships, and the psychosocial and attachment contexts in which

these mechanisms are shaped, organized, and reinforced in ways that lead to developmental trajectories marked by adaptive or maladaptive patterns of relationships, coping, and experiencing.

INTERACTIONAL-INTEGRATING MODELS

Attachment theory has been proposed by a number of authors as a particularly useful framework for conceptualizing the relationship of psychosocial adversity, such as maltreatment and loss, and BPD symptomatology (52). A review of attachment studies in BPD shows an inverse relationship between adult BPD and insecure or disorganized attachment (53,54).

Fonagy et al. (52) suggest that security of attachment is, in turn, linked to the caregiver's mentalizing capacity. Mentalizing refers to the genetically prepared capacity to understand the self and others in terms of intentional mental states, such as thoughts, feelings, needs, desires, and goals. These authors propose that mentalizing is a fundamental maturational achievement underpinning personality development, particularly the capacity for self-agency and the construction of an autobiographical narrative; the ability for social reciprocity and empathy; the capacity for self-regulation and affect modulation; and the capacity to represent experience and symbolize.

Functional neuroimaging studies provide compelling evidence of brain systems mediating mentalization, particularly a neural network including the superior temporal sulcus, the medial prefrontal cortex (including the ACC) and, to a lesser extent, the amygdala and the orbitofrontal cortex associated with BPD (55).

Secure attachment appears to be the optimal and perhaps the necessary developmental context for the unfolding of the psychobiologic capacity to mentalize. At the root of the core symptomatology of BPD appears to lie a diminished capacity to mentalize in the context of attachment relationships (56).

Neurodevelopmental models of BPD have attempted to examine the reciprocal relationship between biologic and psychosocial factors underlying the developmental disruptions postulated to account for BPD.

An example of such models is proposed by Fonagy and Bateman, and Bleiberg (56,57), who advanced the hypothesis that the developmental trajectory leading to BPD comprises the following elements in various combinations: (1) infants with an exceptional disposition to mentalization (hypersensitivity to social cues); (2) a disposition to increased arousal or affective dysregulation associated to neuropsychiatric vulnerabilities, such as mood disorders (58) or ADHD (59); (3) parents who share similar genetic, neuropsychiatric vulnerabilities or histories of maltreatment; (4) a parental disposition to respond to their children's hyperarousal and signals of distress with hyperarousal and distress of their own and inhibition of their capacity to mentalize, interfering with the capacity to accurately match the

children's internal state (60); (5) a corresponding impairment in children's capacity to maintain a stable, mentalized representation of affect and intentionality in self and others in the context of close attachments (56); (6) children's adaptation to stress and relationship trauma with an inhibition of their capacity to deal with mental states, relying instead on prementalistic, coercive maneuvers aiming at achieving self-stability and a sense of attachment; and (7) a reinforcement of this psychological and psychosocial adaptation by changes in neural mechanisms of arousal that lead to a low threshold for the triggering of the arousal system with a concurrent inhibition of the frontal and prefrontal structures involved in mentalizing in response to relatively mild emotional stimuli (61). The prototype of such adaptation appears to be the disorganized pattern of attachment.

Such a model may help explain one of the paradoxes of borderline psychopathology of an uncanny sensitivity and reactivity to other people's mental states, accounting for their exquisite capacity to know what are the right buttons to push in order to evoke responses from others, and the dramatic intensity of their responses to interpersonal events, incongruously coexisting with remarkable self-centeredness and utter disregard for other people's feelings.

Diagnosis and Clinical Features

Beginning in the early 1980s, a number of authors reported on a substantial consensus among clinicians on the diagnostic criteria for borderline children. These clinical criteria closely parallel the adult criteria for BPD.

Petti and Vela (23) described the confusion in the clinical literature between children with borderline personality or borderline spectrum disorders and children who, although often referred to as borderline, are more appropriately described as falling within the schizotypal personality or schizophrenia spectrum disorders. Both groups of children present transient psychotic episodes, idiosyncratic fantasies, and magical thinking. Yet only schizotypal children have a family history of schizophrenia spectrum disorder or present constricted, flat, or inappropriate affect; oddness of speech; and discomfort in social situations, these features contrast with the intense, dramatic affect and hunger for social response of borderline youths. This differentiation is supported by genetic, epidemiologic, and follow-up studies of adult BPD that discriminate BPD from the schizophrenia-schizotypal spectrum.

Clinical Evaluation

Early manifestations of developmental difficulties are apparent in children who subsequently develop BPD, including a difficult temperament, high activity levels, poor adaptability, negative mood, and problems settling into rhythmic patterns of sleep–wakefulness and feeding. Cranky and hard to soothe, these infants frequently

challenge and burden their caretakers.

Hyperactivity and temper tantrums are common in the preschool years of many children on the path to BPD, whereas others are more notable for their clinginess and vulnerability to separations. By school age, these children almost invariably meet diagnostic criteria for an axis I diagnosis, more commonly ADHD, conduct disorder, separation anxiety disorder, or mood disorder.

Many of these youngsters appear anxious, moody, irritable, and explosive. Minor upsets or frustrations trigger intense affective storms—episodes of uncontrolled emotion wholly out of proportion to the apparent precipitant. The lability of their affect mirrors the kaleidoscopic quality of their sense of self and others. One moment they feel elated and expansive, blissfully connected in perfect love and harmony to an idealized partner. Next, they plunge into bitter disappointment and rage coupled with self-loathing and despair.

On clinical examination, school-age borderline children may appear helpless and vulnerable, provocative and suspicious, or eager to comply and ingratiate themselves with the examiner. These youngsters quickly attempt to establish highly coercive, controlling relationships with their examiners (62). Some show surprisingly little anxiety about meeting alone with the clinician and proceed to take over the office as if they owned it. Even those who seem vulnerable and anxious try vigorously to set the agenda for the meeting. They become anxious and even more desperate and arbitrary when the examiner does not comply with their demands or when they feel that their control is threatened. A distorted sense of reality is a distinctive and puzzling feature of borderline children, as they create a vivid fantasy world in which they become intensely absorbed. They then attempt to coerce others to assume certain roles that fit their particular fantasy. While they can generally recognize the arbitrariness with which they treat reality, they behave as if they must believe their own falsification of reality. When others do not match the prescribed roles, borderline children become desperate, enraged, and transiently psychotic.

Psychological testing reveals rigid and tenuous repressive defenses coexisting with primitive defenses; a highly egocentric, arbitrary interpretation of reality; transitory disturbances in reality testing and impairments in formal thought processes in unstructured tests; constant or recurrent disturbances in ego functions, such as frustration tolerance, attention, and goal directedness; primitive, unmodulated experience of affects and drives; and marked disturbances in interpersonal relationships and in the experiences of self and others (62).

The developmental and psychosocial pressures of adolescence typically trigger the onset of the full range of borderline psychopathology and allow for greater diagnostic certainty. Adolescence may be the point at which the coping mechanisms, relationship patterns, and modes of organizing experience acquire self-perpetuating rigidity and the capacity to coercively evoke responses from others that maintain and reinforce these youngsters' maladjustment.

Unstable relationships with peers become prominent as transient idealization and clingy overdependence alternate with rage, devaluation, and feelings of abandonment and betrayal. Regardless of whether idealization or anger predominates, all of their interpersonal exchanges have an intense, dramatic quality. Promiscuity is more common in borderline girls, particularly in sexually abused girls, for whom aggressive seductiveness affords the opportunity to turn around and gain control of the helplessness associated with being abused.

Borderline boys are often burdened with intense shyness and fears of rejection. Manipulative efforts to secure attention and prevent abandonment become prominent interpersonal strategies for both boys and girls. Bulimic binges or drugs are relied on for soothing and comfort and become essential regulators of well-being and self-esteem (63,64). Yet, the transient nurturance derived from food binges, drug abuse, or promiscuous sex only leads to shame, guilt, and a dreaded feeling of inner deadness or emptiness. Self-mutilation and suicidal gestures result from a wish to "feel something" and relieve the emptiness, an effort to escape unbearable feelings of anxiety and depression, a desire to punish a previously idealized partner, and a manipulative attempt to evoke guilt and involvement. Dissociative episodes appear more commonly in sexually abused borderline adolescents.

A central feature of BPD—and all PD—is the construction of a rigid set of beliefs, mental representations, and coping mechanisms. As Zanarini et al. (65) remark, individuals with BPD believe that people cannot be loved comfortably or left gracefully and transform anxiety, sorrow, and rage into indirect, dramatic, reproachful attempts to evoke attention. They anticipate experiencing subjective dyscontrol and fragmentation, so they actively provoke these very experiences, thus gaining an illusion of control over themselves and others. Borderline children's rigid and desperate insistence on inducing interpersonal responses that support and validate their own mental representations and expectations turns into one of the most daunting therapeutic challenges facing child and adolescent clinicians.

The use of well-established interview tools to support clinical assessment is recommended for a reliable diagnosis in adolescents. Structured interviews such as the structured clinical interview for PD is an interview-based assessment that shows good reliability (66) and validity. The Personality Disorder Examination (PDE) a child version of the Diagnostic Interview for Borderline patients (C-DIB) for adolescents (67) and the borderline personality features scale (SCID-II), also show reliability and validity.

For children (BPFS-C) (10) shows good psychometric properties. The BPFS-C includes age-appropriate items adapted from the original scale for adults to reflect the domains of affective instability (e.g., "My feelings are very strong. For instance, when I get mad, I get really, really mad. When I get happy, I get really, really happy"); identity problems (e.g., "I feel that there is something important missing about me, but I don't know what it is"); negative relationships (e.g., "I've picked

friends who have treated me badly"); and self-harm (e.g., "I get into trouble because I do things without thinking"). A newly developed parent report (BPFS-P) has been validated and shows good psychometric properties. An 11-item version has recently been developed for use in large-scale epidemiologic studies or outcomes studies where shorter measures are required (68).

Differential Diagnosis

Adult BPD is often comorbid with other disorders, including major depression, substance misuse, posttraumatic stress disorder, other anxiety disorders, and eating disorders. Evidence is now accumulating of a similar cooccurrence of diagnosis of other PD. The strongest comorbidity demonstrated for BPD is with externalizing disorder (69,70). In one study (71), conduct disorder was the only axis I disorder significantly more prevalent in adolescents with BPD than in those without.

Physical and sexual abuse and early losses are common features in BPD and conduct disorders. ADHD uncomplicated by BPD does not include the array of problems with self-destructiveness, unstable relationships, and fragile sense of reality. Conduct disorders can also be associated with other PD—for example, narcissistic personality disorder—as well as with depression and learning disorders such as dyslexia.

Equally complex is the differentiation between BPD and mood disorders. A vulnerability to affective dysregulation and a proneness to excessive rage may be significant predisposing factors to BPD. Children of bipolar parents present a range of psychiatric difficulties, including conduct disorders, substance abuse, and dysthymia. Clinical descriptions of childhood presentations of bipolar or dysthymic disorders portray moody, irritable, and affectively labile children with a low tolerance for frustration and explosive anger. More definite mood changes in late school-age years or adolescence should point to a diagnosis of mood disorder, particularly exuberant affect, loud giggling, increased activity, disturbed sleep, recent onset of angry outbursts, and decreased attention. Manic adolescents may do poorly in school because of poor concentration or high-flown thinking or end relationships because of irritability or impulsivity. The acute onset of a depressive episode characterized by hypersomnia, psychomotor retardation, and psychosis in a child or adolescent with a family history of two or more generations with mood disorders is predictive of a bipolar course.

A history of trauma, particularly sexual abuse, is common in BPD. PTSD follows exposure to an identifiable, overwhelming stressor. Repeated traumatization can result in a response of reenactment, avoidance, dissociation, and hyperarousal that becomes woven into the child's or adolescent's habitual and pervasive patterns of coping, relating, and experiencing and can contribute to the development of BPD.

Eating disorders, particularly bulimia nervosa, are often part of the clinical

picture of BPD. In younger children, separation anxiety disorder should be differentiated from the clinginess and distress following separations characteristic of borderline youths. Children with an uncomplicated anxiety disorder do not exhibit the impulsivity, rage, self-destructiveness, and impaired sense of reality typical of borderline psychopathology.

The cross-sectional presentation of mood disorders and externalizing disorders (including ADHD and conduct disorder) may mimic BPD. Thus, adequate treatment of the comorbid disorder and a longitudinal perspective is needed before arriving at a dual diagnosis.

Another group of disorders that must be ruled out is schizophrenia spectrum disorders. Transient psychotic episodes, suspiciousness, and a disturbed sense of reality are typical features of BPD, but delusions, hallucinations, and loose associations are not. A family history of schizophrenia spectrum disorders is suggestive of these disorders.

The most common disorders cooccurring with adult BPD include avoidant, dependent, narcissistic, antisocial, and paranoid personality disorders. The child clinical literature often confuses BPD and schizotypal personality disorder. Schizotypal children present magical thinking, unusual perceptual experiences, idiosyncratic fantasies, and paranoid ideation, all common in borderline children. Schizotypal children, however, have a family history of schizophrenia spectrum disorders and present constricted or inappropriate affect, oddness of speech and behavior, and extreme discomfort in social situations, which contrast with the intense and dramatic affect and hunger for social response of borderline youths.

Children with a schizoid disorder of childhood may become intensely absorbed in a world of fantasy of their own making but are not distressed by their social isolation and do not attempt to coerce caretakers and peers to play roles prescribed by their idiosyncratic fantasies or play themes.

Children in the process of developing narcissistic personality or histrionic personality disorders present significant clinical overlap with children with BPD. Narcissistic or histrionic children are self-centered and self-absorbed, need constant attention, respond with rage to rejection or indifference, alternate between idealization and devaluation, are seductive and manipulative, express affect with undue intensity and drama, and, in the case of narcissistic youngsters, are preoccupied with fantasies of power and control. Borderline children, however, display much greater impulsivity, self-destructiveness, affective instability, disturbances in the sense of reality, and transient psychotic episodes.

Course and Prognosis

The few prospective longitudinal studies conducted to assess the course and prognosis of juvenile BPD have shown inconsistent findings. Some studies provide

limited evidence of developmental continuity of BPD symptoms from adolescence into adulthood. But most support a developmental trajectory that begins with childhood externalizing disorder mixed with internalizing disorders leading to adolescent BPD and developing into adult BPD. For example, Crawford et al. (11) examined the developmental link between personality disorder symptoms (borderline, histrionic, and narcissistic) and comorbid internalizing and externalizing symptoms in a community sample of 407 adolescents. Cross-lagged longitudinal models tested the hypothesis that symptoms reflect primary disturbances that give rise to cooccurring internalizing and externalizing symptoms, versus the alternative hypothesis that these axis I symptom clusters reflect primary problems that interfere with normal personality development and lead to dysfunctional patterns of coping and relating. Instead of clearly supporting one hypothesis over the other, longitudinal models suggested gender-specific developmental effects that were partially consistent with both hypotheses.

Current evidence supports the conclusion that adolescence and young adulthood of BPD patients are marked by dramatic crises of affective dyscontrol, interpersonal storms, and impulsive and self-destructive behavior, which often require extensive use of health and mental health resources. Family dysfunction and occupational impairment associated with suicide risk and substance abuse are most notable during the late adolescent and young adult years and tend to decrease in intensity during middle age, a time when a significant percentage of patients with BPD “mellow” and are able to gain greater stability in their relationships.

Treatment

Psychopharmacotherapy

The use of medications can powerfully support the parents’ competence and the alliance between parents and treaters. Randomized controlled trials (RCTs) of pharmacologic interventions with BPD children and adolescents are very limited and thus, pharmacotherapy is largely based on clinical studies and research with adults. Pharmacotherapy is also grounded in clinical experience with these youths and in studies documenting the effectiveness of medications in a range of related or comorbid child and adolescent problems. The role of pharmacotherapy in the treatment of children and adolescents with BPD is to target dysregulations of arousal, cognition, affect, and impulse.

Pharmacotherapy targets both the symptoms that emerge during episodes of acute psychobiologic decompensation and the trait vulnerabilities that represent an enduring diathesis to dysfunction. No one-to-one correspondence has been identified between specific neurobiologic vulnerabilities and types of PD. Thus, given the current level of knowledge, pharmacotherapy targets personality dimensions, such as

affective dysregulation and impulsive-behavior dysregulation, and axis I disorders, such as depression, anxiety disorders, ADHD, and mood disorders. By impacting the neurobiologic underpinnings of arousal, cognition, affect, and impulse, pharmacotherapy creates optimal conditions for psychotherapy and family treatment.

Psychosocial Interventions

Children and adolescents can more readily become engaged in treatment when they are not buffeted by subjective distress, anxiety, or hyperarousal, or when their depressed energy level and reduced capacity for concentration have improved. Parents' position as provider of containment and support is enhanced when they collaborate with the treaters in administering medication effectively.

While BPD is not regularly evaluated or treated in routine clinical practice (72), its assessment and treatment has been identified as an important public health priority. This priority reflects the reality that evidence-based psychosocial treatment for BPD in adolescents is available (10). Prominent in this regard are mentalization-based treatment for adolescents (MBT-A) (63), dialectical behavior therapy (DBT) (73), and cognitive analytic therapy (CAT) (74) for which RCTs have been conducted (63). While these therapeutic modalities share some features, they can be distinguished by the mechanism of change they each assume. MBT assumes that the development of BPD in adolescence is grounded in a phase-specific compromise in the capacity to mentalize that occurs during adolescence. DBT synthesizes a change orientation from behavior therapy with an acceptance orientation from Zen philosophy specifically to target the emotional dysregulation, distress tolerance, and interpersonal difficulties associated with BPD. CAT integrates elements of psychoanalytic object relations theory and cognitive psychology and identifies procedural sequences or chains of events that may include thoughts, emotions, and motivations to explain how a target problem (e.g., interpersonal aggression) is established and maintained.

Recently, focus in BPD intervention has shifted to indicate prevention. This notion is promoted by Chanen et al. who suggest that neither stand-alone universal, nor selective prevention of BPD is currently practical, and argue for indicated prevention that targets adolescents with subthreshold (two or three) symptoms of BPD. Data have begun to emerge to suggest indicated prevention to be a viable option for early intervention in BPD (75).

5.14 GENDER VARIANCE AND GENDER DYSPHORIA

CHAPTER 5.14 ■ GENDER DYSPHORIA AND GENDER INCONGRUENCE

JACK L. TURBAN III, ANNELOU L. C. DE VRIES, AND KENNETH J. ZUCKER

INTRODUCTION

Transgender (gender incongruent) youth include children and adolescents who experience a marked incongruence between their gender assigned at birth and their gender identity (1). Since the last edition of this volume, which was published 10 years ago (2), there has been a remarkable increase in attention to transgender issues across the life span. Television has begun to highlight transgender individuals from childhood to adulthood (3,4). News outlets from *The New York Times Magazine* to *Le Monde* have explored the life experiences of transgender youth (5–7). Legislative bodies have examined transgender rights through restroom access, hate crime legislation, insurance regulations, and antidiscrimination policies, with physicians playing key roles in these discussions (8). Parallel to this growing attention, there has been a marked increase in the establishment of specialized gender identity clinics for children and adolescents in North America and in Europe (9), which likely reflects the marked increase in referrals that has been noted internationally (10–12). At the same time, the scientific literature on gender incongruence has expanded as well, with a flux of new studies on co-occurring psychological functioning, long-term follow-up studies, biologic correlates, and outcomes of medical interventions. Practicing child and adolescent psychiatrists should be familiar with the basics of this field to appropriately assess and treat these patients.

TABLE 5.14.1

TERMINOLOGY

Term	Definition
Gender assigned at birth/natal sex/birth sex	Gender assigned to an infant at birth, generally based on physical characteristics (genitalia, etc.)
Experienced gender/gender identity	An individual's psychological understanding of one's own gender
Affirmed gender	An individual's psychological understanding of one's own gender, typically referring to one who lives socially as that understood gender
Sexuality/sexual orientation	Refers to the types of individuals toward whom one is romantically and/or sexually attracted
Transgender	Refers to an individual whose gender identity is incongruent with that of one's gender assigned at birth. Sometimes also used as a term for an individual whose gender identity is binary opposite one's gender assigned at birth.
Gender dysphoria	Refers to psychological distress in relationship to one's experienced gender; is also the classification used in the DSM 5 (requiring fulfillment of certain

	clinical criteria)
Cisgender	Refers to an individual whose experienced gender matches that of one's gender assigned at birth
Gender non-conforming/gender variant	Refers to variation from developmental norms in gender role behavior that may be considered as nongender stereotypical. This may include identifying as both genders or identifying with neither gender, among others.
Transsexual	Typically used to refer to individuals who desire medical interventions to align their physiologies with the gender identities. This term is used synonymously with transgender by some and has largely fallen out of favor (though it was used commonly in the past).

TERMINOLOGY AND DEFINITIONS

Terminology in this specialized area is continuously evolving. This section describes terms and definitions that are in most common usage at this time, but different regions, cultures, and families may have their own preferred terminology (Table 5.14.1).

The term *gender assigned at birth* refers to a newborn's gender (boy, girl, indeterminate), as generally declared by a medical professional. Other relevant terms include *natal sex* and *birth sex.* The term *biologic sex* is somewhat vague, as it is unclear whether it would be based on karyotyping of the sex chromosomes, internal reproductive structures, the configuration of the external genitalia, etc. The vast majority of newborns are assigned the gender of boy or girl through prenatal diagnostics or, at birth, based on genital anatomy. A small number of newborns may be classified as having a "disorder of sex development" (DSD), or what others have called "differences of sex development" (13), congenital conditions in which biologic parameters of sex (e.g., the sex chromosomes, the gonads or the configuration of the external genitalia, etc.) are incongruent with one another. These conditions include complete or partial androgen insensitivity syndrome, mixed gonadal dysgenesis, 5-alpha-reductase deficiency, penile agenesis, and congenital adrenal hyperplasia (CAH), among others. Such patients may experience gender identity issues that can be unique from those experienced by those without a DSD (14).

Experienced gender refers to one's gendered sense of self as a boy, as a girl, or some alternative gender that is different from the traditional boy–girl dichotomy (e.g., "gender fluid," "agender," or "nonbinary"). Other terms include *affirmed gender* (typically used for individuals who have transitioned socially to living as the desired gender). For the majority of individuals, experienced gender matches the gender assigned at birth. These individuals are referred to as *cisgender.* For some patients, experienced gender is opposite from the gender assigned at birth, and these individuals are referred to as *transgender.*

Transgender, gender variant, and *gender nonconforming* are sometimes used as terms for individuals whose experienced gender does not strictly match that of their

gender assigned at birth. One who experiences psychological distress in relation to one's gender identity may be referred to as *gender dysphoric.* Gender dysphoria is the diagnostic term that has been adopted in the DSM-5 (see below) (1).

Sexual attraction or *sexual orientation* is a separate concept from gender identity. Sexual orientation refers to the types of individuals toward whom one is romantically or sexually attracted. Terms such as androphilia (attraction to males), gynephilia (attraction to females), biphilia (attraction to males and females), and aphilia (attraction to neither males nor females) are used more commonly nowadays, slowly replacing older terms such as heterosexual, bisexual, homosexual, and asexual. In the scientific literature, the sexual orientation of individuals who identify as transgender can be described in relation to their experienced gender or their gender assigned at birth. For example, an adolescent female who identifies as male and is sexually attracted to females can be described as "heterosexual" in relation to experienced gender but as "homosexual" in relation to birth sex (15). From either a clinical or research perspective, it is critical to identify the referent in describing a patient's sexual orientation. Most individuals who identify as transgender will describe their sexual orientation in relation to their gender identity, not their gender assigned at birth (e.g., a transgender woman who is attracted to men would likely consider herself to be heterosexual).

The "genderbread person" has been developed as an educational tool to clarify the distinctions among *gender assigned at birth, experienced gender,* and *sexual orientation* (Figure 5.14.1). Note that as a published educational instrument, this graphic diverges somewhat from the contemporary terminology we described above. Nonetheless, this tool has proven useful for introducing this terminology to families and students new to the topics of gender and sexuality.
FIGURE 5.14.1. The Genderbread Person. The genderbread person is an educational tool used to explain the distinctions between experienced gender (termed gender identity here), gender

assigned at birth (termed biological sex here), and sexual or romantic orientation. This educational tool may be useful for students new to the field and when explaining these phenomena to families with gender incongruent and gender dysphoric children. These terms are further described in Table 5.14.1. (Modified from Killermann S. (2016). *The Genderbread Person*. Available at: itspronouncedmetrosexual.com)

HISTORY OF GENDER IDENTITY AND MEDICINE

John Money (1921–2006) was a psychologist and sexologist whose empirical and theoretical contributions regarding gender identity, gender role, and gender development were innovative and of great influence, beginning in the 1950s. Money originally proposed a theory of "gender neutrality," suggesting that gender identity was predominantly determined by social factors, including the gender assigned at birth and subsequent socialization processes (16). Money proposed that, for individuals with a DSD, early surgical interventions to correct genital ambiguity were often needed so that a child could then be supported with rearing in the gender assigned at birth.

Over the past few decades, Money's original theory of gender neutrality at birth has been challenged by various lines of evidence suggesting the importance of biologic factors, particularly patterns of prenatal hormone exposure, in also contributing to gender identity formation and differentiation. For example, chromosomal females with CAH, assigned female at birth are exposed to elevated levels of prenatal testosterone and many of these girls are behaviorally masculinized and a higher percentage than the general population develop gender dysphoria and transition from male to female (17,18).

Perhaps the most widely cited case pertains to a biologically "normal" male (one of a pair of identical twins) who, after a circumcision accident at the age of 7 months led to penile ablation, underwent a vaginoplasty and was socially reassigned to female at the age of 17 months (19,20).

Although this patient was described by Money (21) as a "tomboy" during childhood, subsequent follow-up revealed that the patient rejected estrogen therapy at the time of puberty and subsequently transitioned back to living as a male (19,20). Tragically, this patient committed suicide at the age of 38 (22). The "John–Joan" case, as it was called, has been used as evidence of the importance of biologic factors in contributing to a person's sense of gender identity. A subsequent summary of seven similar such patients reared as female after traumatic loss of the penis have shown both male and female gender identities in adolescence and adulthood, further complicating the picture (23).

In the 1960s, research into the developmental histories of adults with

"transsexualism" suggested that childhood cross-gender identification was common in these individuals (24). This work was then followed by research with children who showed patterns of gender-related behavior similar to the recalled patterns of transsexual adults (24). During this period, there was much less attention given to adolescents with a marked history of cross-gender identification.

By the late 1990s, however, more attention was given to adolescents with a DSM diagnosis of gender identity disorder, including the possibility of treatments with gonadotropin-releasing hormone analogs (GnRHa), as reported by a research team in the Netherlands (25). This approach, described below, was ultimately outlined in the 2009 Endocrine Society Guidelines for the Treatment of Transsexual Persons (26) and in the periodically updated Standards of Care by the World Professional Association for Transgender Health (27). Research into these hormonal interventions has since garnered significant attention, including increased NIH funding to study the long-term benefits and risks of these endocrine treatments (28).

DIAGNOSIS AND ASSESSMENT

Gender identity diagnoses first entered the DSM in its third edition with three diagnoses: transsexualism, gender identity disorder of childhood, and atypical gender identity disorder. The essential feature of these three diagnoses was "an incongruence between anatomic sex and gender identity" (29). Revisions in the DSM-III-R were modest, though in this edition, exclusion of individuals with schizophrenia or a DSD was removed, noting that individuals with either of these diagnoses could also have a gender identity disorder (30).

In the DSM-IV, the three diagnoses from DSM-III were collapsed into the overarching diagnosis "gender identity disorder" with distinct criteria sets for children versus adolescents and adults. This edition also added a criterion stating "The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning" (31).

The DSM-5 renamed "gender identity disorder" as "gender dysphoria," aiming to decrease stigma associated with the diagnosis while maintaining a diagnosis that could be used to secure access to care for those who needed it (32). The DSM-5 removed sexual orientation subtyping, but noted in the text its relevance in understanding variations in developmental trajectories and for research on biologic factors and long-term outcomes (1). The DSM-5 also made an effort to make the childhood diagnosis stricter, requiring more than just gender nonconforming behavior. The new criteria required that a child expresses an actual desire or insistence of being the other gender. The adolescent and adult criteria simultaneously became more inclusive, allowing for nonbinary gender identities that would allow for gender variant, but not strictly binary, transgender adolescents and adults to receive the diagnosis and subsequently access to care.

Current DSM-5 criteria for gender dysphoria in children require a marked incongruence between one's experienced/expressed gender and assigned gender, of at least 6 months' duration, as evidenced by at least six of eight criteria, one of which must be a strong desire to be of the other gender or an insistence that one is the other gender (or some alternative gender different from one's assigned gender) (1). Additionally, the patient must experience clinically significant distress or impairment in social, school, or other important areas of functioning as introduced in the DSM-IV (Table 5.14.2). DSM-5 criteria for gender dysphoria in adolescents and adults are similar, though with different requirements for the manifestation of gender dysphoria. This diagnosis requires at least two of six manifestations (Table 5.14.3). For a summary and rationale for the DSM-5 changes, see Zucker et al. (33).

Some have argued for use of the term "gender incongruence," including the Working Group on Sexual Disorders and Sexual Health for the forthcoming 11th edition of the International Classification of Diseases. This group suggested that the term gender incongruence highlights that not all transgender individuals experience dysphoria. The group noted that the term gender dysphoria might increase inappropriate stigmatization and pathologization. Only for the practical purpose of preserving access to medical care did the group recognize the necessity of classification. The group additionally argued that the diagnosis be moved out of the chapter on mental health and behavioral disorders and into another section, provisionally termed Conditions Related to Sexual Health (34).

TABLE 5.14.2

DSM-5 CRITERIA FOR GENDER DYSPHORIA IN CHILDREN AND IN ADOLESCENTS AND ADULTS

Diagnostic Criteria
Gender Dysphoria in Children
302.6 (F64.2)

A. A marked incongruence between one's experienced/expressed gender and assigned gender, of at least 6 months' duration, as manifested by at least six of the following (one of which must be Criterion A1):
   1. A strong desire to be of the other gender or an insistence that one is the other gender (or some alternative gender different from one's assigned gender).
   2. In boys (assigned gender), a strong preference for cross-dressing or simulating female attire; or in girls (assigned gender), a strong preference for wearing only typical masculine clothing and a strong resistance to the wearing of typical feminine clothing.
   3. A strong preference for cross-gender roles in make-believe play or fantasy play.
   4. A strong preference for the toys, games, or activities stereotypically used or engaged in by the other gender.
   5. A strong preference for playmates of the other gender.
   6. In boys (assigned gender), a strong rejection of typically masculine toys, games, and activities and a strong avoidance of rough-and-tumble play; or in girls (assigned gender), a strong rejection of typically feminine toys, games, and activities.
   7. A strong dislike of one's sexual anatomy.
   8. A strong desire for the primary and/or secondary sex characteristics that match one's experienced gender.

B. The condition is associated with clinically significant distress or impairment in social, school, or

other important areas of functioning.

Specify if:

- With a disorder of sex development (e.g., a congenital adrenogenital disorder such as 255.2 [E25.0] congenital adrenal hyperplasia or 259.50 [E34.50] androgen insensitivity syndrome).
- Coding note: Code the disorder of sex development as well as gender dysphoria.

Gender Dysphoria in Adolescents and Adults

302.85 (F64.1)

A. A marked incongruence between one's experienced/expressed gender and assigned gender, of at least 6 mo duration, as manifested by at least two of the following:
   1. A marked incongruence between one's experienced/expressed gender and primary and/or secondary sex characteristics (or in young adolescents, the anticipated secondary sex characteristics).
   2. A strong desire to be rid of one's primary and/or secondary sex characteristics because of a marked incongruence with one's experienced/expressed gender (or in young adolescents, a desire to prevent the development of the anticipated secondary sex characteristics).
   3. A strong desire for the primary and/or secondary sex characteristics of the other gender.
   4. A strong desire to be of the other gender (or some alternative gender different from one's assigned gender).
   5. A strong desire to be treated as the other gender (or some alternative gender different from one's assigned gender).
   6. A strong conviction that one has the typical feelings and reactions of the other gender (or some alternative gender different from one's assigned gender).

B. The condition is associated with clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Specify if:

- **With a disorder of sex development** (e.g., a congenital adrenogenital disorder such as 255.2 [E25.0] congenital adrenal hyperplasia or 259.50 [E34.50] androgen insensitivity syndrome).
- **Coding note:** Code the disorder of sex development as well as gender dysphoria.

Specify if:

- **Posttransition:** The individual has transitioned to full-time living in the desired gender (with or without legalization of gender change) and has undergone (or is preparing to have) at least one cross-sex medical procedure or treatment regimen—namely regular cross-sex hormone treatment or gender reassignment surgery confirming the desired gender (e.g., penectomy, vaginoplasty in a natal male; mastectomy or phalloplasty in a natal female).

TABLE 5.14.3

TREATMENT OF TRANSGENDER YOUTH

Timing	Intervention
Prepubertal	No endocrine intervention recommended. Patient should have regular psychotherapy to discuss gender identity and assess possible future need for hormonal intervention.
Early signs of puberty	Pubertal blockade with gonadotropin-releasing hormone analogs to prevent the development of secondary sex characteristics and provide additional time for psychotherapy and consideration regarding partially reversible interventions.
Age 14+ or 16+, depending on the center	Cross-sex hormonal therapy with estrogen or testosterone. Less frequently with other endocrine-acting medications that have less favorable side effect profiles.
Age 18 for most centers	Gender-affirming surgeries may be considered. Note that some surgeries may be performed earlier for select patients (generally mastectomies for transgender males).

EPIDEMIOLOGY OF GENDER DYSPHORIA AND GENDER NONCONFORMITY

A range of methodologic challenges, including but not limited to shifting terminology and stigma associated with self-identification, have made it difficult to establish the true prevalence of gender dysphoria or gender incongruence.

Prevalence in Adults

In adults, most studies have used the numbers of individuals that seek out clinical care for gender-affirming treatment as a proxy for determining prevalence in a certain country or catchment area. A recent meta-analysis based on 21 studies that applied this method concluded that the prevalence of transsexualism (the definition used in most of these studies) was 6.8 transwomen in 100,000 gender at birth-assigned males (1:14,705) and 2.6 transmen in 100,000 gender at birth-assigned females (1:38,461) (35). A time trend was also found, with recent studies reporting higher prevalence rates. These studies are, of course, limited by the fact that they do not include transgender individuals who do not seek medical care. Indeed, much higher prevalence rates, ranging from 4.2% having an ambivalent gender identity to around 0.5% identifying as transgender and considering medical interventions, are suggested by recent studies that have used broader definitions and probability samples (36–38). A recent population-based survey in the United States found that 0.6% of adults self-identified as transgender, with rates ranging from 0.3% to 0.8% in the states for which data were available. Compared to the older age groups, young adults between 18 and 24 years old were most likely to identify as transgender (39).

Prevalence in Children and Adolescents

Although formal epidemiologic studies of gender dysphoria in children and adolescents have not been conducted, looser or more liberal definitions of “caseness” in children and adolescents have been examined in several recent studies. In a random sample of 2,730 grade 6 to 8 students from San Francisco, Shields et al. (40) found that 1.3% self-identified as “transgender” in response to the question “What is your gender?,” with the other response options being female or male. In a random sample of 8,166 high school students from New Zealand, Clark et al. (41) found that 1.2% self-identified as transgender and 2.5% reported that they were not sure about their gender, in response to the question “Do you think you are a transgender?” which was followed by a definition of the term. Interestingly, another 1.7% reported that they did not understand the question.

In the 1999 standardization sample of the Child Behavior Checklist (CBCL) for children aged 6 to 18 years and the Youth Self-Report (YSR) form, aged 11 to 18

years, there is one item pertaining to gender identity ("Wishes to be of opposite sex") (42). On the CBCL (total $N = 3,210$), less than 1% of parents of nonreferred boys and 1.2% of nonreferred girls endorsed this item as either somewhat or sometimes true or very true or often true. The percentages were higher for referred boys and girls (2.8% and 5.4%, respectively). On the YSR, about 10% of nonreferred girls and 2% of nonreferred boys endorsed this item compared to about 18% of referred girls and 3% of referred boys. In the prior 1991 CBCL standardization sample, two age groups were reported (4 to 11 and 12 to 18). For the 4 to 11 year olds, 1% of parents of nonreferred boys and girls endorsed this item compared to 3% and 5% of referred boys and girls. For the 12 to 18 year olds, none of the parents endorsed this item for nonreferred boys and girls compared to 2% and 5% of referred boys and girls. Consistent with the original CBCL and YSR standardization studies, two consistent findings emerge: the item is endorsed more often for girls than for boys and it is endorsed more often for referred than for nonreferred children and adolescents.

Gender Assigned at Birth Ratio

Of prepubertal children referred to gender identity clinics, the majority has a male gender assigned at birth. Among 577 Canadian children referred to a gender identity clinic between 1976 and 2011, the male-to-female ratio was 4.49:1 (12). This was significantly higher than the 2.02:1 ratio in the Netherlands (12). These differences are theorized, in part, to be a reflection of increased parental anxiety regarding gender-variant behavior in males compared to females, particularly in North America. For adolescents with gender dysphoria, the gender ratio is much closer to 1:1 and appears to be more consistent across nations (10). Of note, however, there has been a recent temporal shift from more birth-assigned males (prior to 2006) to more birth-assigned females (2006 to 2013), though the ratio remains closer to 2:1 in either direction (10).

BIOLOGIC AND PSYCHOSOCIAL DETERMINANTS

The etiology of cross-gender identification and behavior continues to be elusive. While psychological and social factors were once the focus of study, especially in normative gender development, attention has shifted to biologic mechanisms more recently. At present, the evidence suggests that both psychosocial and biologic elements are involved. A monocausal mechanism is unlikely and gender dysphoria most likely results from a complex interaction between these factors (43).

Biologic Factors

Twin studies suggest a strong heritable component with additional environmental

contributors. In a large-scale CBCL study of Dutch twins (*N* = 23,393) ages 7 and 10 (44), monozygotic (MZ) and dizygotic (DZ) twins were compared and estimated genetic factors contributed to 70% of cross-gender behavior (as assessed via the two CBCL gender items). Another study of 314 MZ and DZ twins (mean ages 9.4 and 10.1 years, respectively) roughly replicated this finding, with genetic factors contributing to 62% of the variance on a DSM-IV-based gender dysphoria scale (45). In a third study of 3,337 Japanese MZ and DZ twins ranging in age from 3 to 26 years (46), there was also strong evidence for genetic factors for females, but much less so for males.

Many studies, both in animals and humans, have shown that differences in brain anatomy and function in cis-gender males and females underlie the sex differences in their behavioral (47). Sex hormones play an important role in these differences. The *organizational* effect, predominantly prenatally but also during puberty, leads to the sex differences in brain structures. On average, males have larger brain volumes, more white matter, gray matter, and cerebrospinal fluid than females, although when corrected for total volume, females have more gray matter and a larger volume of the cortex (48–50).

The sexual differentiation hypothesis suggests that transgender individuals may have brain structures and brain functioning more closely aligned with their experienced gender (51). Postmortem studies have suggested a sex reversal in several hypothalamic nuclei in transgender adults (52,53). More recent neuroimaging techniques have allowed the in vivo study of brain morphology and functioning of larger numbers of adolescents and adults with gender incongruent feelings (50,54). Findings of these studies are more mixed. Before they received any medical gender affirmative treatment, brain anatomy with regard to volume, gray and white matter, and cerebrospinal fluid did not differ compared to their birth-assigned sex (50). Differences are, however, found with regard to the white matter microstructure, with results of transgender individuals in between males and females (50). In the realm of functional neuroimaging, task-related imaging studies show that transgender people may have either similar reactions as their experienced gender (e.g., smelling odorous steroids (55)) or activity different from their assigned gender as well as their experienced gender (e.g., mental rotation (56)), or not different from their assigned gender (e.g., verbal fluency (57)). The results so far show that we are still far away from a situation where imaging or other medical testing may serve as a diagnostic tool.

In animal studies, where prenatal hormones can be manipulated, the strong effect of prenatal testosterone on gender role behavior is clear (47). The effects on gender identity, however, can only be studied in humans. Individuals with DSD may be exposed to high levels of prenatal testosterone, and XX individuals with CAH (58) indeed have higher rates of gender dysphoria and cross-gender identification (18). The majority of female-raised individuals with CAH (~95%), however, appear to

develop a female gender identity (17). Other evidence for the importance of prenatal testosterone comes from studies in XY individuals with complete androgen insensitivity syndrome (CAIS) who lack the receptors necessary to respond to endogenous testosterone. The vast majority of these patients develop a female gender identity, suggesting that downstream testosterone signaling may be important for the development of a male gender identity (59). Others have noted that these patients are reared unambiguously as females and that social factors may play a strong role in their female identity formation (60). Some studies have shown that those with CAIS have lower scores on tests of female identity scales (61) and there have been some case reports of gender dysphoria ultimately leading to gender-affirming surgeries (62). This notably could be secondary to the psychological stress of learning about the diagnosis, as well as the possibility of undetected functional androgen receptors (43). Overall, studies of gender identity in individuals with DSD, while implicating androgens in the development of gender identity, have yet to show a simple direct relationship.

Psychosocial Factors

Past literature has investigated the potential role of parental characteristics on the development of gender dysphoria (maternal wish for a child of the opposite gender, paternal absence, and parental psychological functioning, among others). None of these hypotheses have been validated (43). Mothers of gender dysphoric boys have been noted to have higher scores on the Beck Depression Inventory and the Diagnostic Interview for Borderlines (63), but these higher scores might be due to external pressures placed on these parents by unaccepting social environments and such studies cannot determine the direction of causation. One study noted that gender dysphoric boys were rated as more feminine and "beautiful" by blinded college students (64) while another study of gender dysphoric girls showed that these girls were rated as less "cute" (65), raising the question of whether perceived physical appearance and resultant social treatment may contribute to gender incongruence. An alternative interpretation of this data is that those with a more male gender identity might alter their appearances to appear more "masculine" (e.g., culturally masculine haircuts) while those with a more female gender identity alter their appearances to appear more "feminine" (66). Some have suggested that a lack of parental limit-setting, particularly around cross-gender behavior, is associated with gender dysphoria (67), though this again does not prove causation, as more insistence on cross-gender behavior (i.e., transgender identity or stronger cross-gender behavior preferences) may make this limit-setting more difficult. Overall, there have been no proven causative psychosocial factors in the development of gender incongruence. Since studies on normative gender identity development show that cognitive psychological factors and social environment play a role, this may also be the case

for gender nonconforming development.

CLINICAL COURSE

Persistence of Gender Dysphoria from Childhood to Adolescence

The natural history of gender identity for children who express gender nonconforming or transgender identities is an area of active research (68). To date, the long-term follow-up studies of clinic-referred children have been based on samples that have included children who were either threshold or subthreshold for the gender identity diagnosis in DSM-III, III-R, or IV and some of the earliest studies began prior to the availability of formal diagnostic criteria.

These follow-up studies have classified participants as either "persisters" or "desisters" with regard to their cross-gender identification, using various metrics (semi-structured interviews based on DSM criteria for gender identity disorder, dimensional scores on standardized questionnaires, etc.). Ristori and Steensma (69) have provided the most recent summary of 10 follow-up studies, in which the percentage of participants classified as persisters ranged from 2% to 39% (collapsed across natal boys and girls). In one study (70), the percentage of natal girls who were persisters appeared to be substantially higher than the percentage of natal boys (50% vs. 12%), but in two other studies from the same clinic, the percentage was similar across natal sex (71,72).

One criticism of these studies is that either formal diagnostic criteria were not used (because they were not available at the time of the study) or that subthreshold cases were included. Some studies have found that threshold cases were more likely to be classified as persisters (73), but other studies have not (72). It has also been suggested that more recent cohorts (after the year 2000) have found higher rates of persistence (12% to 39% (61,64–66)) than older cohorts (2% to 9% prior to 2000 (74,75)); however, it is not clear if such differences are related to variations in sampling procedures or something more substantive. Comparisons of persisters with desisters have found that the intensity of gender dysphoria (using dimensional metrics), older age at the time of assessment in childhood, a lower social class background, and having a female gender assigned at birth are associated with higher rates of persistence (72,73). Despite this work, it remains difficult to predict, for an individual child, the likelihood of cross-gender identification persistence from childhood into adolescence (73).

Persistence of Gender Dysphoria from Adolescence to Adulthood

In contrast to the low rates of persistence from childhood into adolescence, it appears that the vast majority of transgender adolescents persist in their transgender identity (76).

Childhood Gender-Variant Behavior and Sexual Orientation

Childhood gender-variant behavior has been found to be a strong predictor of a same-sex sexual orientation (using gender assigned at birth as a reference point) in adults. In a study of 879 Dutch boys and girls, gender-variant behavior was assessed using the CBCL and sexual orientation was assessed 24 years later (77). It was found that the prevalence of a same-sex sexual orientation was, depending on the domain (attraction, fantasy, behavior, and identity), between 8.4 and 15.8 times higher in the gender-variant subgroup as compared to the nongender-variant subgroup. In summary, the current literature, though limited as described above, suggests that the majority of gender incongruent prepubescent children will grow up to identify as cisgender individuals with either a bisexual or a same-sex sexual orientation (70,72,74).

ASSOCIATED COEXISTING PSYCHIATRIC CONDITIONS AND BEHAVIORS

Children and adolescents with gender incongruence exhibit higher internalizing and externalizing psychopathology as compared to nonreferred controls, with internalizing psychopathology being more common, particularly in natal boys (78–84). One hypothesis is that this problem behavior is a result of minority stress and dysphoria toward their gender assigned at birth. These individuals are also subjected to rates of peer bullying as high as 80% (85). Poor peer relations is one of the strongest investigated predictors for behavioral and emotional problems in gender incongruent youth (79). In a study of 105 gender dysphoric Dutch adolescents whose parents completed the Diagnostic Interview Schedule for Children (DISC), 32.4% had one or more psychiatric disorders, with 21% suffering from anxiety, 12.4% from mood disorders, and 11.4% from disruptive disorders (85). A study with the same DISC measure in prepubertal children revealed higher percentages, with 52% having one or more psychiatric disorders other than GD (80).

Chart review studies of gender incongruent youth presenting to specialized gender identity clinics have shown similarly high or even higher rates of psychiatric conditions: mood (12.4% to 64%), anxiety (16.3% to 55%), and disruptive disorders (9% to 11.4%) (82,83,86–88). The prevalence range across studies may be secondary to cultural differences, differing diagnostic criteria, and differing ages of clinical populations. These psychiatric conditions appear to become more common in

gender incongruent individuals with increasing age. Some studies have shown that older transgender youth suffer a greater burden of co-occurring psychiatric conditions (82), and that gender incongruent adults suffer a greater burden of co-occurring psychiatric conditions as compared to adolescents (89).

Self-harming Behavior and Suicidality

Self-harming behavior and suicide attempts are prevalent among gender incongruent youth. Gender clinics have reported high rates of past suicide attempts by patients presenting for care: Boston (9.3%, mean age 14.8 (87)), London (10%, mean age 13.5 (82)), Los Angeles (30%, mean age 19.2 (86)). Rates of self-harm and suicidality appear to increase with age within this population (90).

Autism Spectrum Disorder

A number of studies have shown autism spectrum disorder (ASD) symptoms to be over-represented among transgender individuals. Clinical level rates of ASD symptomatology in transgender adults have been reported in the range of approximately 5% to 20% (91–93). A single study of 204 children and adolescents referred for gender dysphoria reported an ASD prevalence of 7.8% as measured by the Diagnostic Interview for Social and Communication Disorders (94). This compares to rates of ASD in the general population of around 1% (95). Two studies found increased gender variance (5.4%, 11.3%), defined by a positive response to "wishes to be of opposite sex" sometimes or often on the CBCL or YSR) in referred children, adolescents, and adults with ASD compared to nonreferred controls (96,97). However, the same was true for an ADHD-referred control sample (97), raising the issue that a higher probability of gender variance is characteristic of clinic-referred samples in general. Several hypotheses for shared underlying etiology that explains the link between these two conditions have been suggested (98–100).

Clinically, the co-occurrence of gender dysphoria and ASD may complicate transgender care, as diagnosing gender dysphoria can be difficult (e.g., in the context of the rigid thinking that is characteristic of ASD). Case reports have described instances cross-gender identification represented a transient preoccupation in youth with ASD (101). Additionally, language difficulties can make expression of gender dysphoria difficult for patients with ASD. Nonetheless, a comprehensive narrative review of the literature has shown a role for transition with pubertal blockade and cross-sex hormonal therapy in these patients following an extended diagnostic process (99). By use of a Delphi method, a group of experts on the ASD-gender dysphoria co-occurrence developed initial clinical guidelines assessment and treatment for adolescent transgender care (98). Careful diagnosis of both conditions by specific specialists, collaboration of clinicians from both fields, an extended

diagnostic phase, and risk assessment and safety issues are part of the suggested management protocol.

THERAPEUTICS

Treatment of Prepubescent Children

Over the past 10 years, best practice treatment for children with gender dysphoria has been the subject of intense controversy (102). As noted below, there are now three broad approaches that have been delineated in the literature: (1) the oldest one —characterized by Dreger (103) as the “therapeutic model”—consists of efforts, either directly (e.g., via specific suggestions that parents can implement in the day-to-day environment) or indirectly (e.g., psychodynamically informed approaches that treat the putative underlying “causes” of the gender dysphoria) and actively attempt to reduce cross-gender identification (104); (2) an intermediate approach, which some have characterized as “watchful waiting” (105), in which no direct efforts are made to “prohibit” a child’s gender-variant behavior, but one that also advises parents to keep options open about the child’s long-term gender identity and to avoid early social transition; (3) and, more recently, an approach characterized by Ehrensaft (106) as the “affirmative model” that considers all outcomes of gender identity to be equally valid and desirable and allows children who express a desire to socially transition to do so after careful counseling. These approaches have been discussed in great detail in three Task Force reports (107–109), in a special volume of the *Journal of Homosexuality* (102), and various other essays and case reports, the references for which can be found in these major reviews.

For the nonspecialist, there are several key issues to keep in mind when appraising this literature: (1) Some of these approaches may be influenced by particular theoretical formulations regarding the determinants of gender dysphoria and these formulations guide or influence recommended treatment plans; (2) there are no randomized controlled trials that have compared the effects of these treatments with regard to both short-term and long-term outcomes. Indeed, Byne et al. (109) noted that, by and large, “the highest level of evidence … can best be characterized as expert opinion” (p. 762); (3) with some rare exceptions (110), there are no manualized or even semi-manualized treatments that a clinician can follow in developing a therapeutic plan. Thus, the clinician needs to self-educate by reading about the therapeutic model that one intends to follow and tailor it on a case-by-case basis. Below, we provide relatively brief summaries of these three treatment approaches.

Promoting Identification with the Gender Assigned at Birth

This first approach aims, through psychosocial interventions, to reduce the child's cross-gender identification and gender dysphoria. These treatments (which have been described in the literature since the 1960s) have, however, been quite varied. They include classical behavior therapy, psychodynamic therapy (including psychoanalysis and dynamically informed play psychotherapy), parental counseling, and parent-guided interventions in the naturalistic environment (e.g., encouragement of peer relations of the same natal sex) (110,111).

Perhaps the underlying assumption of all of these approaches rests on the view that gender identity is not yet fixed in childhood and may be malleable through psychosocial treatments. There is also an implicit assumption or value judgment that might be inferred from this approach, namely that all things considered a child's long-term adaptation might be easier if he or she could come to feel content with a gender identity that matches their natal sex and to avoid the necessity of a lifelong regimen of cross-sex hormonal treatment and sex-reassignment surgery (or what nowadays is also called gender-affirming surgery).

Critics of this approach have argued that there is nothing inherently "wrong" with a cross-gender identity and have challenged the view that trying to change such an identity is warranted. Indeed, there are now several US states and one province in Canada that have passed legislation stating that it is inappropriate to try and change a minor's gender identity when the minor is unable to consent to the treatment, but exempt from this directive is "identity exploration" (112). Critics have also rightly noted that some of the earliest proponents of this treatment held the belief that it might also reduce the odds of the child's later development of a same-sex sexual orientation (113), although other proponents of this treatment rejected this as an ethically defensible treatment goal (111). Another expressed concern has been that this type of treatment might cause a child to feel shame or other negative and maladaptive feelings (108).

Watchful Waiting

The second approach takes an intermediate therapeutic position. On the one hand, it does not recommend an early gender social transition on the grounds that the extant follow-up studies have shown that the majority of children with gender dysphoria desist for one reason or another. On the other hand, it does not explicitly recommend any type of limit-setting on the child's gender-variant behavior, with the exception that in certain environments it might be risky or dangerous to display such behavior, which Hill et al. (114) described as the "only at home" rule.

This approach also does not privilege one type of long-term outcome over another, noting that it is difficult to predict outcome for an individual child and that the more important focus should be on the child's general psychosocial adjustment and well-being. This approach does, however, include recommendations to parents that they try to encourage in their child a variety of gender-related interests and social

affiliation with children of both genders. In some respects, the “watchful waiting” label is a bit of a misnomer because clinical protocols appear to include information provided to the parents that is more than “wait-and-see.” As noted by de Vries and Cohen-Kettenis (115), appropriate limit-setting with good explanation of why the limits are set to their child may be helpful so that the child will learn “that not all desires will be met,” which is important because “someone’s deepest desire or fantasy to have been born in the body of the other gender will never be completely fulfilled.” Although social transition according to this approach is not recommended at a very young age, an increasing number of children have already socially transitioned when they come to gender identity clinics (115). Some of these children may have no clear memories of a time that they were socially living in the birth-assigned gender and have stopped talking about being born different from their experienced gender. In these cases, it is encouraged that parents create an open situation where the child has the possibility of returning to the birth-assigned gender. It is discussed with the child that when gender identity feelings change, it is nothing to be ashamed of, that nobody will be angry, that the child may speak out, and that it is good to have tried. A form of psychotherapy that helps the child to verbalize his or her feelings may be advised so that, by the time the child may come back for GnRHa, the child is able to talk about his or her feelings and can give informed consent.

Affirmative Approach

The affirmative approach theorizes that clinician and parental attempts to push children with gender incongruence toward conforming to their gender assigned at birth might produce shame and stigma that can ultimately lead to internalizing psychopathology (108). The approach considers all outcomes of gender identity to be equally desirable and affirms any gender identity the child expresses.

Though similar to the watchful waiting approach, an important departure is in its approach regarding early social transition. In the affirmative model, prepubertal children who ultimately express a desire to socially transition and live full time in their experienced gender (i.e., using cross-gender pronouns, a cross-gender name, cross-gender clothing, etc.) are allowed to do so. The approach to social transition must be carefully individualized with a nuanced understanding of the child’s gender identification and the level of support within the child’s community; there must also be an open discussion with the child highlighting that despite the social transition that the patient is free to transition back at any time (115).

Some have noted cases where this transition back to living as one’s birth gender can be particularly difficult mostly due to fear of peer judgment (116), though this must be weighed against the potential negative consequences of refusing to affirm a child’s identity and desire to transition socially. The affirmative model predicts that this lack of affirmation might lead to shame and consequent internalizing

psychopathology (117). The therapeutic relationship in these cases could also be negatively affected if the clinician strongly discourages an early transition for a patient who ultimately persists in cross-gender identification.

Critics of social transitions in prepubertal children have raised the question of whether early social transition increases the rates of gender incongruence persistence from childhood into adolescence. Indeed, a multivariate regression analysis revealed that early social transition was associated with persistence (73). However, the direction of this association cannot be determined by this study. While some believe that prepubertal social transition makes children more likely to persist, the alternative interpretation is that those likely to persist are also more likely to undergo early social transition, due to currently unidentified factors. This additionally raises the ethical question of whether persistence should be considered an undesirable outcome. The affirmative model suggests that all outcomes of gender identity are equally desirable.

Separate from the question of persistence is the question of mental health outcomes following social transition. There is a relative paucity of literature studying the effect of prepubertal social transition. One study examined 73 American prepubertal children who were transgender in a binary fashion and allowed to socially transition. Parents of these children completed short forms for anxiety and depression at an unspecified time following the transition (118). Data from these scales revealed that these children had notably lower rates of internalizing psychopathology than previously reported children who did not transition. Furthermore, socially transitioned children in this study showed developmentally normal levels of depression and only minimally elevated (subclinical) levels of anxiety. It is important to note that families in this study had a relatively high median income, raising the question of whether this cohort is representative of a broader sociodemographic cohort (119). Though this early work suggests that socially transitioned children have better mental health metrics than previously reported children who did not socially transition, future research is needed to fully understand the dynamic and long-term effects of social transition in a broader population (119).

Treatment of Adolescents

Once children have reached puberty, transgender identity persists in the vast majority of cases, and medical intervention is often considered. At present, the effectiveness of an approach that includes puberty suppression and is followed by cross-hormones and surgeries has been evaluated in two studies on the same cohort of Dutch adolescents. The first study evaluated gender dysphoria and psychological functioning at two time points; first, when the 70 adolescents entered the clinic (mean age, 13.65 years), and second, just before they started cross-hormones (mean age, 16.64 years). Of interest, while adolescents improved with regard to psychological

functioning on several domains, gender dysphoria did not improve and all adolescents went on with the next step of gender-affirming hormones (120). The second study added a third assessment, around one year after gender affirmative surgeries, when the first 55 adolescents who had been in this treatment protocol had reached young adulthood (mean age, 20.70 years). This time, gender dysphoria was resolved and psychological functioning measures had even further improved with scores that were comparable to normative samples. The same accounted for quality of life, subjective happiness, and satisfaction with life scores (121). These positive results are promising and give trust that starting treatment at a relatively young age is possible. However, the results come from only one clinic and concern a highly selected sample that received support from their parents and often their further school and social environment that started the treatment only after extensive assessment and received further mental health counseling during the years of treatment. Whether the same positive results can be expected for the larger number of adolescents that are treated at clinics that strongly vary in their approach to gender-variant adolescents has yet to be determined.

Assessing Eligibility

According to Endocrine Society Guidelines, hormonally based medical intervention may be initiated at the earliest signs of puberty (i.e., Tanner 2 or 3) (26). Other eligibility criteria include meeting criteria for gender dysphoria (termed gender identity disorder in the 2009 guidelines), experiencing dysphoria toward early pubertal changes, having adequate psychological and social support for treatment, understanding the risks and benefits of treatment, and not suffering from a psychiatric comorbidity that would interfere with treatment (26). To assess eligibility, most clinics offer an assessment by a mental health professional that sees the adolescent and his or her family over a longer period of time before decisions regarding medical interventions are made. This time is used to prepare for the long period of medical treatment with lifelong consequences that is likely to follow and weigh the pros and cons of treatment so that an informed decision can be made. Although many adolescents come with a clear wish for medical treatment, some are not sure yet and want to explore their gender dysphoric feelings more broadly. Sometimes co-occurring psychiatric difficulties like ASD with rigid thinking, severe depression with acute suicidality or anxiety with worrisome avoidance and school refusal, complicate this diagnostic work and make coming to regular medical checkups and taking medication impossible. Treatment of these psychiatric disorders may then be necessary before endocrine intervention. The importance of parental support for the psychological well-being of adolescents is widely acknowledged (122). The time that is used for assessment may also be helpful in addressing parents' concerns and improving the adolescent–parent relationship. The time that is needed before medical intervention is provided may vary for each individual case, but tends to be longer

when psychosocial comorbidities occur (115,123).

Fully Reversible Interventions (Pubertal Blockade)

The first such intervention (implemented at Tanner 2 or 3 of puberty) is pubertal blockade with GnRHa. Gonadotropin-releasing hormone is produced by neurons in hypothalamus. In prepubertal children, this hormone is secreted at very low levels. At the initiation of puberty, release of gonadotropin-releasing hormone becomes cyclical. This cyclical release of hormone results in release of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) from the anterior pituitary. These hormones then enter the peripheral circulation, where they initiate the production of sex hormones (estrogen in natal women and testosterone in natal men). These hormones then initiate the irreversible development of secondary sex characteristics.

GnRHa (either implants, depot injections, or regular injections) maintain high levels of gonadotropin-releasing hormone in the circulation. Without physiologic cyclical fluctuations in GnRH levels, FSH and LH are not released and all downstream signaling is prevented. This allows the patient to remain in a prepubertal state (124).

Pubertal blockade prevents the development of irreversible secondary sex characteristics (voice deepening, breast development, etc.) and provides additional time for gender dysphoric children to decide if they wish to fully transition physically into the body of the opposite sex. Therefore, it does not need to be considered actual gender affirmative medical treatment, but rather may function as an extended diagnostic phase. If the GnRHa implant is removed or the injections discontinued, the effects of the medication are reversible. With removal or discontinuation of the GnRHa, the patient will undergo natal puberty. Follow-up studies into young adulthood on the first cohort of puberty-suppressed adolescents are reassuring with regard to side effects. Although there was some deprived bone density, there were no concerns regarding liver and kidney functioning and lipid profile (125,126). Some advise clinicians to evaluate bone age for these patients every 3 months (26) and have regular blood monitoring to ensure that the central axis of puberty is sufficiently suppressed (26).

Partially Reversible Interventions (Cross-sex Hormonal Therapy)

Around the age of 16, patients may choose to move onto the next intervention of cross-sex hormonal therapy with estrogen or testosterone, according to Endocrine Society guidelines. Some groups have noted that cross-sex hormones can be instituted earlier, as delaying puberty outside the developmentally appropriate age may cause social problems for these youth (127). Additional criteria for cross-sex hormonal therapy are identical to those for GnRHa in the Endocrine Society guidelines.

Cross-sex hormones will initiate the development of secondary sex characteristics

of the desired puberty. These interventions are mostly irreversible and carry a more significant side-effect profile. The most prominent side effect of estrogen therapy is hypercoagulability, though clinicians prescribing these medications should be aware of the full spectrum of side effects. Of note, this hypercoagulability can be particularly problematic for patients undergoing high-risk surgery such as vaginoplasty. Patients on these medications should be regularly monitored for serum hormone concentrations and maintained within normal testosterone and estrogen serum concentrations for their desired gender. Spironolactone has been used for its antiandrogenic properties in select cases but is generally not considered a first-line treatment given its unfavorable side-effect profile as a diuretic (26).

Irreversible Interventions (Gender-Affirming Surgeries)

At the legal age of adulthood, patients may choose to undergo a variety of surgical interventions, including vaginoplasty, phalloplasty, scrotoplasty, breast augmentation, facial reconstruction, hysterectomy, reduction thyroid chondroplasty, among others. Patients should be carefully counseled on the risks and benefits of surgery. Specific surgical interventions are many and are out of scope for the purpose of this review. Of note, some surgical interventions may be considered earlier in the course of treatment. In the WPATH's Standards of Care, mastectomies are being considered earlier than age 18 (27).

Fertility Considerations

There is a paucity of research on the effects of pubertal blockade and cross-sex hormonal therapy on future fertility. Interested patients should be counseled on fertility preservation options early in treatment. Include LGBT Health study showing that most transgender youth do not desire fertility preservation, however most adults which they had. More longitudinal research needed (128).

SUMMARY

Gender incongruent and gender dysphoric youth represent a vulnerable demographic with high rates of co-occurring psychiatric conditions and suicidal behavior, likely secondary to minority stress and dysphoria related to living in a body that does not match one's experienced gender. Prepubescent children with gender-variant behavior or identification are best supported with psychotherapy. For those children who continue to have strong cross-sex identification in adolescence, pubertal blockade, and cross-sex hormone therapy to align patients' bodies with their identities have been shown to improve mental health outcomes.

5.15 NEGLECT, ABUSE, AND TRAUMA-RELATED CONDITIONS

CHAPTER 5.15.1 ■ CHILD ABUSE AND NEGLECT

JOAN KAUFMAN AND DANIEL HOOVER

INTRODUCTION

If you work in mental health, you work with maltreated children. The best available data suggest that approximately 30% of child and adolescent outpatients (1), and as many as 55% of child and adolescent psychiatric inpatients have a lifetime history of abuse or neglect (2). While not all abused children go on to develop psychiatric problems, a history of abuse is a highly significant risk factor for the development of a number of different psychiatric disorders (3,4), as well as a notable risk factor for a host of medical health problems later in life (5).

This chapter reviews definitions and prevalence of child abuse and neglect. It also discusses developmental, clinical, and neurobiological sequelae of child maltreatment, and findings from the fields of genetics, epigenetics, and neuroscience relevant for understanding risk, resilience, and recovery. A number of treatment interventions are also reviewed.

DEFINITIONS

Each state has its own definitions of child abuse and neglect that are based on minimal standards set by federal law. Definitions of the various maltreatment categories have also been drafted by the American Academy of Child and Adolescent Psychiatry (6). Federal legislation defines child abuse and neglect as (7):

> *Any recent act or failure to act on the part of a parent or caretaker which results in death, serious physical or emotional harm, sexual abuse or exploitation; or an act or failure to act, which presents an imminent risk of serious harm.*

Most states have laws pertaining to the four major types of maltreatment: physical abuse, sexual abuse, psychological maltreatment, and neglect. While physical abuse, the nonaccidental injury of children is unlawful nationwide, corporal punishment is allowed in the home of birth families in every state. It is not allowed in most out-of-home placement settings though. As of June 2014, 40 states prohibited the use of corporal punishment in foster homes or institutions (8). Given the state-by-state variation in legal standards, clinicians should familiarize themselves with the maltreatment criteria and corporal punishment laws specific to the state where they practice.

PREVALENCE

The federal government has been analyzing annual data on child abuse and neglect since 1990 (9). Between 1990 and 1994, the number of annual cases of child abuse and neglect that were substantiated rose from 861,000 to 1,032,000 (10). Since 1994, the rates of substantiated cases of maltreatment have declined, with only 679,000 confirmed cases of maltreatment reported in the most recent recorded year (9). These 679,000 cases were from 3.5 million referrals of families for suspected maltreatment involving approximately 6.4 million children.

The decline in rates of child maltreatment is believed to be "real," and has been attributed to prevention efforts, more aggressive criminal prosecution of perpetrators, and increased dissemination of psychiatric medications targeting behaviors that increase risk for abuse (11). It is likely, however, that some of the drop in substantiation rates is an artifact of changing practices and standards for responding to allegations of maltreatment (12), as there have been no corresponding decreases in rates of referrals for suspected maltreatment, or rates of child abuse–related fatalities during this same time period (13). Specifically, 1994, the year rates of substantiated reports of maltreatment began to drop, is the same year states began to implement differential response programs (14). Differential response programs, also referred to as alternative responses or family assessment programs are part of a two-tier response to allegations of abuse and neglect that have been implemented in most states. The most severe maltreatment allegations involving injury or imminent risk still involve forensic evaluations and determination of whether or not maltreatment occurred, but moderate- to low-risk cases are referred for family assessments instead. The goal of the contact is no longer a formal determination of whether abuse or neglect occurred, but rather an evaluation of whether or not services are needed to strengthen families.

Preliminary data from research conducted on differential response programs suggest child safety is better served by this alternative approach to responding to child maltreatment allegations. Families who receive differential response family assessments have fewer subsequent maltreatment reports, a longer period of time between re-reports, and less severe new reports than families receiving traditional protective services forensic investigative interventions. Differential response interventions are also associated with greater family satisfaction, and most importantly, greater involvement with community services (15).

While the true rate of abuse and neglect will likely never be known (16), a synthesis of self-report studies suggests official documented rates of abuse and neglect grossly underestimate the true prevalence of these experiences (17). There are many reported cases of actual abuse that are not verified (18), and countless other cases which never come to the attention of authorities (19).

ASSESSING CHILD ABUSE, NEGLECT, AND OTHER TRAUMA EXPERIENCES

Given the high prevalence of maltreatment experiences in child psychiatric populations (1,2), psychiatric assessment of children should routinely include screening for abuse, neglect, and other traumatic experiences (20). It is best to assess children's trauma experiences utilizing information from multiple informants (e.g., parent, children, child protective service workers) (21–23). Rating scales to facilitate assessment of child abuse, neglect, and other traumatic experiences are reviewed in the Chapter 5.15.2 of this text.

NEW DISCLOSURES OF CHILD MALTREATMENT

Mental health providers are mandated reporters. They are required by law to report suspected abuse and neglect. Unfortunately, there is no systematic research on optimal procedures for handling mandated reporting requirements. In our clinical experience, it is usually best to inform the parent or guardian of one's intention to file a report, and to suggest that the parent or guardian call in the information and report the concerns as well. The parent's response to this fact will provide valuable information in evaluating the parent's capacity to support and protect the child, and determine the safety of the child staying in the immediate custody of the parent. It also gives the parent a sense of control at a very stressful time, and in truth, protective service workers look favorably upon a parent who calls to report the problem independently. Regardless of whether the parent agrees to call in the alleged maltreatment or not, the mental health professional is obligated to make the report.

As the process of case investigation can be idiosyncratic (24), it is recommended that detailed information about the alleged abuse and known risk (e.g., prior reports of maltreatment, parental substance abuse, domestic violence, number of birth to 3-year-old children living in the home) and protective (e.g., parent engaged in treatment, extended positive family supports) factors be included in suspected child maltreatment reports. Clinicians should not attempt to conduct forensic evaluations in the context of clinical assessments though, as specific guidelines must be followed for forensic evaluations (20,25).

RISK FACTORS FOR CHILD MALTREATMENT

Child abuse most often occurs in the context of other risk factors. Child abuse can and does occur across all socioeconomic classes, but is most prevalent among the poor (26). While most poor families do not maltreat their children, poverty is a significant risk factor for child abuse and neglect, with more than half of the families

participating in a large-scale representative sample of protective services cases falling below the federal poverty line (27).

Substance abuse and domestic violence are two other problems that frequently co-occur in association with child maltreatment. It is estimated that 60% of cases involved with protective services have histories of severe domestic violence (27), and 60% to 70% of parents with substantiated child welfare cases, and more than 80% of parents who lose custody of their children have a substance use disorder (28). These co-occurring problems significantly complicate the management of child maltreatment cases.

SEQUELAE

Indices of Adaptive Functioning

A history of maltreatment is associated with deficits on numerous indices of adaptation across the lifecycle. When compared to community controls, maltreated children have significantly more disturbances in attachment relations in infancy, delays in autonomous functioning and deficits in frustration tolerance in toddlerhood, and problems with self-esteem and peer relations in later childhood (29). Problems in language development and school performance have also been reported, including below average standardized achievement test scores, frequent repeated grades, low cumulative grade point averages, and significant social and behavior problems in the school setting (30). In studies examining resiliency in maltreated children (31,32), a quarter or fewer children could be classified resilient when multiple domains of functioning were considered.

Sexual Behavior Problems

Sexual behavior problems are frequently utilized as indicators of child sexual abuse. While inappropriate sexual behaviors are strongly related to experiences of sexual abuse, they are also associated with histories of physical abuse, witnessing domestic violence, inappropriate exposure to family sexuality, and child psychiatric illness (33). Table 5.15.1.1 delineates behaviors that are highly suggestive of a possible sexual abuse history, behaviors that are relatively prevalent in abuse victims and psychiatric controls with no history of abuse, and behaviors that are frequently observed in these high-risk groups and normal controls (33,34).

Intergenerational Transmission of Abuse

Victims of child maltreatment are more likely than controls to be involved in intimate partner violence in adolescence (35) and adulthood (36). They are also more likely

to experience teen parenthood (37), and have difficulties parenting their own children. While approximately 80% to 90% of abusive parents have a history of child maltreatment, and being abused puts one at risk of experiencing parenting problems, retrospective (38) and prospective longitudinal (39) studies estimate that only one in three individuals who were abused as children repeat the cycle in the next generation. Most break the cycle—or there would be exponential increases in rates of abuse with each generation.

TABLE 5.15.1.1

DISTINCTIVENESS OF SEXUALIZED BEHAVIORS IN INDICATING ABUSE HISTORY

Moderately Prevalent in Sexually Abused Children, Exceedingly Rare in Psychiatric and Normal Controls	Moderately Prevalent in Sexually Abused Children *and* Psychiatric Controls, Uncommon in Normal Controls	Moderately Prevalent in Sexually Abused Children, Psychiatric Controls, *and* Normal Controls
Puts mouth on sex parts	Stands too close to others	Talks flirtatiously
Asks to engage in sexual acts	Hugs adults they do not know well	Masturbates with hand
Masturbates with an object	Talks about sexual acts	Touches sex parts at home
Inserts objects in vagina or anus	Wants to watch movies that show nudity	Tries to look at nude pictures/undressing people
	Knows more about sex than other children their age	

Psychiatric Diagnoses and Symptomatology

Child maltreatment is a nonspecific risk factor for multiple forms of psychopathology (4,40,41). Compared to community controls, maltreated children have elevated externalizing and internalizing behavior problems according to parent and teacher reports (42). They also have increased rates of posttraumatic stress disorder (PTSD) (43); depression diagnoses (44,45); reactive attachment disorder and disinhibited social engagement disorder (46); dissociative symptoms (47); suicidality, self-destructive behavior, and borderline traits (48); drug and alcohol problems (4,49); eating disorders (50); oppositional defiant disorder (51); and conduct disorder and sociopathy later in life (51).

GENETIC PREDICTORS OF PSYCHIATRIC PROBLEMS IN MALTREATED CHILDREN

Genetic factors, in part, appear to explain why some maltreated children go on to develop certain psychiatric problems, and others do not. Caspi et al. were the first to show that risk for antisocial behavior in individuals maltreated as children was moderated by genotype—in particular, variation in the neurotransmitter-metabolizing enzyme monoamine oxidase A (*MAOA*) gene (52). Since this seminal study, there

have been over a hundred studies published that examined gene by environment (GxE) interactions and the moderating effects of various candidate genes on a range of mental health outcomes among individuals with a history of abuse (41). Consistent with other data in the field showing that genetic markers do not map on to distinct DSM diagnoses, but rather individual genetic markers are associated with a range of psychiatric disorders (53), results of the GxE candidate gene studies with maltreated cohorts demonstrate pleiotropy in the genetics of stress-related psychiatric disorders, with each candidate gene examined associated with a variety psychiatric disorders.

As reviewed elsewhere (41), the greatest number of studies in the field have examined genetic variation in the serotonin transporter (*5-HTTLPR*) gene, and replicated reports have found variation in *5-HTTLPR* predicts a range of outcomes. Specifically, among individuals with a history of child abuse and neglect, genetic variation in *5-HTTLPR* has been found to predict risk for depression, PTSD and other anxiety disorders, substance use problems, and antisocial behavior in children and adolescents and aggressive behavior in adults. While not as many studies have been conducted examining the moderating effect of other candidate genes, there is also evidence for pleiotropy in studies examining genetic variation in *MAOA,* the catechol-O-methyltransferase (*COMT*) gene, brain-derived neurotropic factor (*BDNF*) gene, corticotropin-releasing hormone receptor (*CRHR1*) gene, and the FK506 binding protein 5 (*FKBP5*) gene (41).

Genome-wide association studies (GWAS) that have examined predictors of PTSD have also identified genetic markers that interact with trauma history that show evidence of pleiotropy (41). For example, the first PTSD GWAS conducted reported an association between PTSD and the retinoid-related orphan receptor alpha (*RORA*) gene (54), a gene which has also been associated with multiple other psychiatric disorders including depression, bipolar disorder, attention-deficit hyperactivity disorder (55), and autism (41).

Pleiotropy may be due to overlapping symptoms across diagnoses (56,57), or the high rates of comorbidity among disorders (58), which is true even among disorders that share no common symptoms (59). Alternatively, a central tenet of the National Institute of Mental Health Research Domain Criteria (RDoC) initiative is that pleiotropy and comorbidity occur because the various DSM diagnoses are associated with abnormalities in interlocking brain circuits (60). Using an RDoC framework that incorporates dimensional assessments of behaviors that map onto discrete brain circuits, would likely help to advance research on the genetics of stress-related psychopathologies (61).

Advancing the genetics of stress-related psychiatric outcomes will also likely require incorporating emerging understandings of the various mechanisms of gene regulation that affect disease risk. As reviewed elsewhere (41), three of the five other published PTSD GWAS identified unique markers in intergenic nonprotein coding regions of the DNA that predicted risk for PTSD in individuals with a history

of abuse or other lifetime traumatic experiences. Many intergenic regions are enriched for factor-binding sites and are involved in the three-dimensional organization of the genome and gene regulation (62). Transcription factor-binding sites and chromatin insulators within intergenic regions are believed to mediate intra- and interchromosomal interactions, affecting gene expression at both proximal and distal locations (62). Epigenetic modifications in intergenic regions have been implicated in other neuropsychiatric diseases as well (63). As less than 2% of the over three billion DNA base pairs in the human genome code for proteins, it is not surprising that a role in gene regulation and disease risk is emerging for intergenic regions of DNA.

CHILD ABUSE AND EPIGENETIC MECHANISMS OF DISEASE RISK

There is an emerging appreciation of the role of epigenetic mechanisms in understanding how experiences of abuse can confer risk for deleterious outcomes later in life (64,65). Epigenetic processes do not result in genetic mutations, but rather chemical modifications to the DNA that alter gene expression. While some epigenetic modifications are hardwired and responsible for producing cell-specific phenotypic differences, emerging research suggests that the genome is highly sensitive to environmental influences that can promote epigenetic changes. DNA methylation, histone modifications, and posttranslational regulation of gene expression via noncoding RNA species are three different epigenetic mechanisms by which adverse experience such as childhood trauma can alter gene expression, with the most available data examining the role of early adversity on epigenetic changes via DNA methylation (64).

Research by Weaver, Meaney, and colleagues provided the first evidence that variations in early maternal care could produce stable alterations of DNA methylation, providing a mechanism for the long-term effects of early adversity (66). Utilizing a rat model of neglect, operationalized as decreased maternal pup licking and grooming and arched-back nursing, Meaney et al. found offspring of “neglectful” mothers had increased DNA methylation of the glucocorticoid receptor gene in the hippocampus when compared to offspring of “non-neglectful” mothers. The glucocorticoid receptor in the hippocampus is key for putting the brakes on the stress response, and DNA methylation of this gene leads to fewer available glucocorticoid receptors, which is associated with greater stress reactivity and anxiety- and depressive-like behaviors in the rat pups. These behavioral differences emerge early in life and persist into adulthood, and through a series of elegant experiments epigenetic changes programmed by early experience were shown to be causally related to the negative outcomes (66). This was the first series of studies to show that deviations in early experience could alter gene expression that mediated long-term

negative physiological and behavioral outcomes.

Over the past decade there have been at least 40 preclinical and human studies published examining the impact of early adversity on methylation in the glucocorticoid receptor gene (67), and numerous other studies examining the impact of early adversity on expression of a wide variety of genes across multiple brain regions and in the periphery (e.g., blood and saliva DNA) (41). It is now well established that experience can alter gene expression. Results of these preclinical and clinical studies suggest adverse experiences early in life are associated with changes in gene expression of multiple known candidate genes, genes involved in DNA transcription and translation, and genes necessary for brain circuitry development, with changes in gene expression reported in key brain structures implicated in the pathophysiology of psychiatric and substance use disorders (41).

NEUROIMAGING STUDIES IN ABUSED AND NEGLECTED CHILDREN

While there are inconsistencies in the literature, as recently reviewed by Bick and Nelson (68) and Teicher and Samson (69), experiences of child abuse and neglect are associated with structural and functional brain changes across multiple brain regions and circuits that mediate a wide variety of social, emotional, and cognitive processes. Hippocampal volume deficits are one of the best replicated findings in adults with maltreatment-related PTSD; although these deficits have been less consistently observed in pediatric cohorts (68,69). One of the best replicated findings in pediatric cohorts is atrophy of the medial and/or posterior portions of the corpus callosum, with reduced integrity of white matter tracts in this region also reported (69). Relatively consistent findings are also emerging which suggest maltreatment-related changes in corticolimbic circuitry involving enhanced amygdala activation in response to threat stimuli (69), with changes in threat processing circuitry in maltreated cohorts observed in association with depressive, anxiety, and PTSD symptoms, and independent of psychopathology. Several studies have also reported maltreated individuals have a blunted response in the striatal regions in response to anticipated reward in the monetary incentive delay task (69), with reduced activity in the striatal region during this reward task associated with the later development of alcohol problems (70). Preliminary data suggest structural and functional brain changes associated with child maltreatment may vary as a function of family loading for psychopathology (71), genetic variation (72), the age when the experiences occurred (73), and the presence or absence of positive social supports (74).

REVERSIBILITY OF BRAIN CHANGES ASSOCIATED WITH

While brain changes associated with early adversity can be long-lasting, there are emerging data that they can be reversed (75). The notion that early deviant experience can lead to permanent changes in brain development and behavior stems partly from the groundbreaking experiments on monocular deprivation in cats by Wiesel and Hubel (76). The development of central visual pathways in several mammalian species, like many other brain systems, is known to be experience-dependent. Wiesel and Hubel deprived kittens of vision in one eye for different lengths of time and at different ages. They found that after suturing one lid during the first 3 months of life, there was no vision in that eye later in development after the sutures were removed, and the visual cortex did not develop normally. The effects of visual deprivation on subsequent brain development and visual processing was evident only in kittens, not in adult cats, which led to the conclusion that vision development in kittens has a "critical period," and if the eyes are not exposed to the required stimuli during that period, vision would be lost and associated brain structures altered permanently.

Emerging findings, however, are challenging previous understandings of the impact of early experience on brain function and development (75). Further studies revisiting the initial experiments of Wiesel and Hubel have shown that the brain alterations associated with monocular deprivation are due to epigenetic changes, and the effects can be reversed with pharmacologic interventions and environmental enrichment (75). What was previously deemed to be permanent brain damage secondary to adverse early experiences during formative periods of development has now been shown to be amenable to treatment, allowing complete function to be restored.

There are emerging data that some of the brain changes associated with a history of child maltreatment can also be remediated with therapeutic foster care interventions (77–79), and preliminary data that the availability of positive social supports can diminish risk for alterations in key brain circuits affected by experiences of child maltreatment (74). In addition, in a study with adults with PTSD secondary to military trauma, exposure therapy was associated with normalization of fear circuitry functioning in the amygdala and other key brain regions (80). Comparable pre- and posttreatment imaging studies have yet to be conducted in child cohorts, but the findings are promising.

PROMOTING RESILIENCE AND RECOVERY IN MALTREATED CHILDREN

Promoting resilience and recovery in maltreated children is facilitated by: (1) promoting the development and maintenance of positive attachment relationships; (2)

providing enrichment opportunities; and (3) child and birth parent–focused clinical interventions. Data related to each of these are discussed briefly in the following sections.

Attachment

In our work and the work of others, the availability of positive stable social supports has emerged as one of the most important factors in promoting resilience in maltreated children. In our studies with maltreated cohorts, the availability of a positive stable attachment figure has been found to decrease risk for the development of depressive disorders (44), minimize hypothalamic–pituitary–adrenal (HPA) stress axis abnormalities (44), ameliorate the negative effect of genes associated with risk for psychopathology (81), and reduce the negative impact of abuse and neglect on brain structure and function (74,82).

Dozier et al. have developed an attachment-based intervention to facilitate the establishment of secure attachments for infants and toddlers who enter the child welfare system (83). As maltreated infants who enter the system frequently have a history of insecure attachments and multiple disruptions in parenting, these infants may not elicit caregiver support and may actually initially avoid or reject their foster parents' attempt to provide comfort. The intervention, called the Attachment Biobehavioral Catch-up (ABC) intervention, is designed to help caregivers provide nurturance even when children do not elicit it, and even when it does not come naturally to them. The ABC intervention is associated with improvements evaluated into the preschool years in attachment relations (84), measures of affect regulation (85), cognitive flexibility (86), and HPA stress axis indices (87).

Attachment and the availability of stable caring adult caregivers are important across the lifecycle (88). Despite federal legislation passed in 1997 to promote adoptions and permanency for children involved with the child welfare system (89), approximately 25,000 children "age-out" of the foster care system each year without consistent or stable adults in their lives, with approximately 25% of these youth age 12 or younger when they entered care, and more than 30% of them with histories of having experienced eight or more placements before aging out of the system (90). As clinicians working with these youth, helping youth to identify and maintain positive stable supports is an important component of the treatment planning process.

Enrichment

Environmental enrichment in early adolescence has been found to ameliorate the negative effects associated with maternal separation and low licking and grooming "neglectful" rearing in rodents studies (91). In a study of matched samples of foster care alumni (92), alumni from the enhanced foster care program had significantly

fewer psychiatric problems as young adults than alumni from public sector foster care programs. The enhanced foster care program provided a greater number of enrichment opportunities for youth, like participation in summer day camp programs, music lessons, and involvement in sports. While the two foster care programs differed in numerous other significant ways, involvement in enriching extracurricular activities provides youth an opportunity to develop positive self-esteem and establish supportive relationships with coaches and other adults who can become meaningful resources for the youth. In addition, there are emerging data that exercise (93) and music training (94) can promote positive brain changes via neuroplasticity. While more data are needed to demonstrate that enrichment experiences can positively impact the outcome of maltreated children, in our clinical experience these types of experiences appear invaluable in tipping the scale in favor of positive outcomes.

Child and Birth Parent Clinical Interventions

Trauma Informed Systems of Care

While it has been acknowledged for decades that parents involved with the child welfare system have high rates of childhood trauma, it is only within the past 5 to 10 that this knowledge has started to shape practice. Emerging data now suggest when mental health and child welfare systems do not appropriately assess, identify, and address underlying trauma issues, services are often more expensive and less effective (95). For further information, the interested reader is referred to the Child Traumatic Stress Network website for state-of-the-art updates on trauma-informed practices (http://www.nctsnet.org).

Posttraumatic Stress Disorder Treatments

PTSD treatment interventions are discussed in greater detail in the Chapter 5.15.2 of this text. Briefly, trauma-focused cognitive-behavioral therapy (TF-CBT) is the intervention with the strongest evidence base for the treatment of PTSD and other trauma-related psychopathology in children (96). In one study that provided TF-CBT to children in foster care (97), compared to children who received treatment as usual, children who received TF-CBT had significantly greater reduction in PTSD and other emotional and behavioral symptomatology, and were half as likely to disrupt from their current foster care placement. Providing trauma-informed care and involving foster parents in children's clinical interventions appear to be essential in promoting continuity of care and facilitating recovery (98).

Interventions That Target Physically Abusive Parenting Behaviors

Parent–child interaction therapy (PCIT) is the therapeutic intervention with the

strongest results in reducing physically abusive parenting behaviors (99,100). PCIT is a model of intervention which was originally developed for young children with externalizing behavior problems that combines concrete teaching and "bug-in-the-ear" coaching to help caregivers interact more effectively with their 2- to 7-year-old children (101). PCIT has shown strong evidence of effectiveness in terms of improving child behavior, and reducing self-reported parental stress, harsh parenting behaviors, child welfare referrals, and recurrence of physical abuse (99,100). Perhaps the main drawback of PCIT is the high dropout rate, especially in families with the most severe child behavior problems, maltreatment, and court-mandated participation (99). Home-based PCIT (102) or utilizing initial motivational sessions prior to implementing PCIT (103) have been shown to enhance treatment completion.

Psychopharmacology

A number of papers have been published raising concerns about the rate of psychotropic drug use among children in the foster care system (104–107). In a large sample of over 15,000 births to 19-year-old children with Medicaid insurance, 30% of the children and adolescents in the sample who were living in foster care were reported to be prescribed psychotropic medications, a rate nearly double the rate of psychotropic drug use among youth receiving supplemental security income (SSI) for diagnosed disabilities, and 15 times the rate of youngsters receiving welfare (105). Another study reported that 41% of the foster care children on psychotropic drugs were prescribed three or more different types of medications (e.g., stimulant, antidepressant, antipsychotic), with atypical antipsychotic drugs used at very high rates (107). In another report, comparably high rates of psychotropic drug use and polypharmacy were documented among youth aging out of the system, however, 41% of the adolescents diagnosed with ADHD and 19% of the youth with a history of mania were not on any medications (108). This raised doubts about the overall appropriateness of medication use in children within the child welfare system, with concerns about both overuse and underuse.

This growing body of research was the impetus for federal legislation requiring states to track and monitor psychotropic drug use among children in the child welfare system (109,110). States were required to develop protocols, not just for the monitoring of psychotropic medications, but for their appropriate uses as well. As recently as 2007, only three states maintained databases to monitor the use of psychotropic medications of children in state custody (111); finding out what drugs children were prescribed required workers in most states to hunt and peck through random case notes.

In a recent survey of key informants from child welfare and affiliated agencies in 47 states and the District of Columbia (112), two-thirds of states adopted at least one "red flag" marker signaling a need for heightened scrutiny. The most commonly used red flags were use of psychotropic medications in young children (defined variously

as 3 to 6 years old), endorsed by nearly one-half of the states; use of multiple concurrent psychotropic medications (defined variously as three to five medications), endorsed by two-fifths of the states; and use of multiple medications within the same class for longer than 30 days, endorsed by two-fifths of the states. Dosage exceeding maximum recommendations (e.g., manufacturer, professional, federal, or state) and medications inconsistent with current recommendations (e.g., professional or state guidelines) were endorsed as red flags by more than one-fourth of the states.

At the time of the survey, most states had or were developing a written policy on the appropriate use of psychotropic medication for youth in the child welfare system (112). But what is the appropriate use of psychotropic medications for youth in state custody due to abuse and neglect? Meta-analyses of adolescent and adult treatment studies have found, compared to individuals who meet criteria for the diagnosis of major depression without a history of child abuse, individuals with a history of child abuse who meet criteria for depression are less likely to remit following standard evidence-based pharmacological (e.g., selective serotonin reuptake inhibitor medications) interventions (45). Individuals with a history of child maltreatment also appear to have a poorer treatment response across a range of diagnoses (113). The database steering the existing guidelines is limited, and will be discussed further in Chapter 5.15.2 of this text. The bottom line is the drugs are being used without a truly adequate research database in maltreated cohorts to guide clinical practice.

Parent-Focused Interventions

As noted earlier in this chapter, an estimated that 60% to 70% of parents with substantiated child welfare cases, and 80% or more of parents whose children are placed in foster care, meet criteria for a substance use disorder (28). Among child welfare cases, parental substance abuse is associated with higher rates of child revictimization, greater likelihood of out-of-home placement, longer stays in care, and higher rates of termination of parental rights and child adoption (28). As reviewed elsewhere (28), over the past decade there has been a burgeoning of research aimed at improving the effectiveness of substance abuse interventions for parents involved in the child welfare system, and addressing parental substance abuse is key to promoting positive outcomes in youth.

CONCLUDING REMARKS

A history of maltreatment puts children at risk for a host of negative outcomes. Over the past decade there have been remarkable advances in the field in terms of dissemination of evidence-based practices to treat trauma-related psychopathology, and insights regarding the mechanisms by which experiences of abuse confer risk for a broad range of psychiatric and medical health problems. Data to guide best

practices in terms of pharmacological treatments are sorely lacking, and an absence of services to address child and parent problems leaves far too many children lost in the child welfare system.

Child maltreatment cases are frequently quite challenging, presenting with high rates of diagnostic comorbidity and co-occurring family and social problems. As discussed previously, recent data suggest that as many as 25,000 children "age-out" of the foster care system each year without consistent or stable adults in their lives, with approximately 25% of these youth age 12 or younger when they entered care, and more than 30% of them with histories of eight or more placements. Through multidisciplinary research efforts with foci that span from neurobiology to social policy, we can, and must do better.

CHAPTER 5.15.2 ■ POSTTRAUMATIC STRESS DISORDER

DANIEL HOOVER AND JOAN KAUFMAN

Deshawn is a 9-year-old African-American boy who resides in his maternal great-grandmother's care along with his younger brother, James, in an urban neighborhood. The brothers were placed with relatives 8 months ago, after witnessing an altercation between their mother and her boyfriend, which ended in their mother's death. The boys' father has been incarcerated for several years and they have had no contact with him since his arrest. While James is making a relatively positive adjustment following his mother's death, Deshawn initially refused to talk about it, then showed increasing irritability, withdrawal, and angry blow-ups at home and school. He has been getting into fights with other children, has trouble concentrating on schoolwork, and has difficulty going to sleep at night. During a diagnostic interview, Deshawn reported having frequent nightmares since his mother's death, some specific to traumatic memories, and some nonspecific. Deshawn has also had illusory experiences of "hearing noises" in the house and worries that someone is trying to break in. He thinks that his misbehavior was the cause of the fight that led to his mother's death.

Deshawn is displaying a constellation of symptoms characteristic of posttraumatic stress disorder (PTSD). His irritability, explosiveness, and nightmares are common features of PTSD. His self-blame, concentration difficulties, and concerns related to safety are symptoms that are also frequently observed in children with PTSD. The difference between his and his brother's adaptation following his mother's traumatic death is also not atypical. As will be discussed later in this chapter, there are many factors that make some children more prone than others to develop PTSD following traumatic events.

This chapter reviews the diagnosis, assessment, and treatment of PTSD in children and adolescents. Data on the genetics, epigenetics, and neurobiology of PTSD and other stress-related disorders are reviewed in the Child Abuse chapter of this text.

ACUTE STRESS DISORDER AND POSTTRAUMATIC STRESS DISORDER DIAGNOSTIC CRITERIA

The DSM-5 places trauma- and stressor-related disorders in their own category (1); previously acute stress disorder (ASD) and PTSD were included with the anxiety disorders. The diagnoses contained in the trauma- and stressor-related disorders section of the DSM include: PTSD, ASD, reactive attachment disorder, disinhibited

social engagement disorder, the adjustment disorders and other unspecified trauma-related disorders. These diagnoses are distinct from other disorders in the DSM in that they require exposure to overt stressors or potentially traumatic events (PTEs) to attain the diagnoses, and the etiology of the diagnoses is specifically linked to the adverse life experiences. The diagnostic criteria for ASD and PTSD are delineated in Table 5.15.2.1.

Exposure to Traumatic Events

As noted above, the diagnoses of ASD and PTSD require exposure to a PTE. In the DSM-5 this is defined as "actual or threatened death, serious injury, or sexual violence." This may be through direct experiencing; witnessing the event(s) in person; learning that the traumatic event(s) happened to a close friend or family member; or "repeated or extreme exposure" to aversive details of the traumatic event(s), like that experienced by first responders. Television or other electronic media exposure to traumatic events does not qualify for the diagnoses of ASD or PTSD.

TABLE 5.15.2.1

DSM-5 CRITERIA

Acute Stress Disorder	Posttraumatic Stress Disorder
A. Exposure to actual or threatened death, serious injury, or sexual violence in one or more of the following ways: 1. Directly experiencing the traumatic event(s). 2. Witnessing, in person, the event(s) as it occurred to others. 3. Learning that the traumatic event(s) occurred to a close family member or close friend. In cases of actual or threatened death of a family member or friend, the event(s) must have been violent or accidental. 4. Experiencing repeated or extreme exposure to aversive details of the traumatic event(s) (e.g., first responders collecting human remains; police officers repeatedly exposed to details of child abuse). *Note:* Criterion A4 does not apply to exposure through electronic media, television, movies, or pictures, unless this exposure is work related. B. Presence of nine (or more) of the following symptoms: Intrusion Symptoms: 1. Recurrent, involuntary, and intrusive	A. Exposure to actual or threatened death, serious injury, or sexual violence in one or more of the following ways: 1. Directly experiencing the traumatic event(s). 2. Witnessing, in person, the event(s) as it occurred to others. 3. Learning that the traumatic event(s) occurred to a close family member or close friend. In cases of actual or threatened death of a family member or friend, the event(s) must have been violent or accidental. 4. Experiencing repeated or extreme exposure to aversive details of the traumatic event(s) (e.g., first responders collecting human remains; police officers repeatedly exposed to details of child abuse). 5. *Note:* Criterion A4 does not apply to exposure through electronic media, television, movies, or pictures, unless this exposure is work related. B. Presence of one (or more) of the following intrusion symptoms associated with the traumatic event(s), beginning after the traumatic event(s) occurred: 1. Recurrent, involuntary, and intrusive distressing memories of the traumatic event(s).

distressing memories of the traumatic event(s).

Note: In children, repetitive play may occur in which themes or aspects of the traumatic event(s) are expressed. Also, in children less than six, spontaneous and intrusive memories may not appear distressing.

2. Recurrent distressing dreams in which the content and/or affect of the dream are related to the traumatic event(s).

Note: In children, there may be frightening dreams without recognizable content.

3. Dissociative reactions (e.g., flashbacks) in which the individual feels or acts as if the traumatic event(s) were recurring. (Such reactions may occur on a continuum, with the most extreme expression being a complete loss of awareness of present surroundings.)

Note: In children, trauma-specific reenactment may occur in play.

4. Intense or prolonged psychological distress or marked physiologic reactions at exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event(s).

Avoidance Symptoms:

5. Efforts to avoid distressing memories, thoughts, or feelings about or closely associated with the traumatic event(s).
6. Efforts to avoid external reminders (people, places, conversations, activities, objects, situations) that arouse distressing memories, thoughts, or feelings about or closely associated with the traumatic event(s).

Negative Mood and Dissociative Symptoms:

7. Persistent inability to experience positive emotions (e.g., inability to experience happiness, satisfaction, or loving feelings).
8. Inability to remember an important aspect of the traumatic event(s) (typically due to dissociative amnesia and not to other factors such as head injury, alcohol, or drugs).
9. An altered sense of the reality of one's surroundings or oneself (e.g., seeing oneself from another's perspective, being in a daze, time slowing).

Note: In children, repetitive play may occur in which themes or aspects of the traumatic event(s) are expressed. Also, in children less than six, spontaneous and intrusive memories may not appear distressing.

2. Recurrent distressing dreams in which the content and/or affect of the dream are related to the traumatic event(s).

Note: In children, there may be frightening dreams without recognizable content.

3. Dissociative reactions (e.g., flashbacks) in which the individual feels or acts as if the traumatic event(s) were recurring. (Such reactions may occur on a continuum, with the most extreme expression being a complete loss of awareness of present surroundings.)

Note: In children, trauma-specific reenactment may occur in play.

4. Intense or prolonged psychological distress at exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event(s).
5. Marked physiologic reactions to internal or external cues that symbolize or resemble an aspect of the traumatic event(s).

C. Persistent avoidance of stimuli associated with the traumatic event(s), beginning after the traumatic event(s) occurred, as evidenced by one or both of the following:

1. Avoidance of or efforts to avoid distressing memories, thoughts, or feelings about or closely associated with the traumatic event(s).
2. Avoidance of or efforts to avoid external reminders (people, places, conversations, activities, objects, situations) that arouse distressing memories, thoughts, or feelings about or closely associated with the traumatic event(s).

D. Negative alterations in cognitions and mood associated with the traumatic event(s), beginning or worsening after the traumatic event(s) occurred, as evidenced by two (or more) of the following:

1. Persistent inability to experience positive emotions (e.g., inability to experience happiness, satisfaction, or loving feelings).
2. Inability to remember an important aspect of the traumatic event(s) (typically due to dissociative amnesia and not to other factors such as head injury, alcohol, or drugs). This item is not included in the criteria for children six and below.
3. Persistent and exaggerated negative beliefs or expectations about oneself, others, or the world (e.g., "I am bad," "No one can be trusted," "The world is completely dangerous,"

Arousal Symptoms:

10. Irritable behavior and angry outbursts (with little or no provocation) typically expressed as verbal or physical aggression toward people or objects.
11. Hypervigilance.
12. Exaggerated startle response.
13. Problems with concentration.
14. Sleep disturbance (e.g., difficulty falling or staying asleep or restless sleep).

C. The duration of the disturbance (symptoms in criterion B) is 3 days to 1 mo after trauma exposure.

"My whole nervous system is permanently ruined"). This item is not included in the criteria for children six and below.

4. Persistent, distorted cognitions about the cause or consequences of the traumatic event(s) that lead the individual to blame himself/herself or others. This item is not included in the criteria for children six and below.
5. Persistent negative emotional state (e.g., fear, horror, anger, guilt, or shame).
6. Markedly diminished interest or participation in significant activities.
7. Feelings of detachment or estrangement from others. This item is behaviorally anchored as "socially withdrawn" for children six and below.

Note: For children six and below, only one symptom is required from the combined set of items included in criterion C and criterion D.

E. Marked alterations in arousal and reactivity associated with the traumatic event(s), beginning or worsening after the traumatic event(s) occurred, as evidenced by two (or more) of the following:
1. Irritable behavior and angry outbursts (with little or no provocation) typically expressed as verbal or physical aggression toward people or objects.
2. Reckless or self-destructive behavior. This item is not included in the criteria for children six and below.
3. Hypervigilance.
4. Exaggerated startle response.
5. Problems with concentration.
6. Sleep disturbance (e.g., difficulty falling or staying asleep or restless sleep).

F. Duration of the disturbance (criteria B, C, D, and E) is more than 1 mo.

Symptom Clusters

In addition to exposure to a traumatic event, the diagnosis of PTSD requires the presence of symptoms from four categories: reexperiencing, avoidance, negative alteration of cognition and mood, and hyperarousal symptoms. The negative alteration of cognition and mood symptom cluster is new with the DSM-5, as is the reckless and the self-destructive behavior item in the hyperarousal symptom cluster. The diagnosis in children over age 6 and adults requires at least one reexperiencing, one avoidance, two negative alteration of cognition and mood, and two hyperarousal symptoms. The diagnosis of PTSD also has two subtype specifiers, one based on the presence of predominant dissociative symptoms and the other based on the timing of PTSD onset (e.g., acute vs. delayed onset).

Acute Stress Disorder

The diagnosis of ASD utilizes many of the same symptoms required for the diagnosis of PTSD. Nine symptoms are required for the diagnosis of ASD, however, they can be derived from any of the symptom clusters. ASD symptoms typically begin immediately after the trauma, but persistence for at least 3 days and up to a month is needed to meet ASD criteria. If the symptoms persist beyond 1 month, a diagnosis of PTSD is indicated.

Diagnostic Criteria for PTSD for Children Ages 6 and Younger

Specific modifications are delineated for diagnosing children of age 6 and younger with PTSD. The exposure and reexperiencing criteria are essentially unchanged from the adult and older child criteria. The diagnosis of PTSD in young children, however only requires one symptom from a combined set of items including the two avoidance symptoms included in the adult and older child criteria, and four of the seven symptoms included in the adult and older child negative alteration of cognition and mood symptom items. The first three items in this section of the adult and older child criteria are omitted from the young child criteria (e.g., inability to remember events, exaggerated negative beliefs, distorted cognitions), given limitations in young children's ability to describe internal thoughts, and the feelings of detachment item were behaviorally anchored (e.g., socially withdrawn) to enhance the appropriateness of this symptom with young children. Like with adults and older children, two hyperarousal symptoms are required for the diagnosis of PTSD in children of age 6 and younger, although the reckless and self-destructive behavior item is omitted from the hyperarousal set of criteria developed for young child. Adopting these changes in diagnostic criteria for young children results in greater temporal stability of diagnosis (2) and a higher, but likely more accurate, prevalence rate of PTSD in young children (3,4).

PREVALENCE

Exposure to PTEs and Rates of PTSD among Adolescents

A recent national survey of US adolescents (5,6) estimates that 61.8% of youth in the United States are exposed to at least one PTE by age 17. This rate of trauma exposure is similar to that found in other previous samples (7). Lifetime prevalence of PTSD among adolescents is considerably lower than rates of trauma exposure and estimated at 4.7%, with significantly higher rates of PTSD observed among females (7.3%)

than males (2.2%) (8). The most common PTEs for children and adolescents are the unexpected death of a loved one (28.2%) and man-made or natural disasters (14.8%), with these PTEs associated with the lowest rates of subsequent PTSD. Only 10.3% of youth exposed to the unexpected death of a loved one, and 6.5% of youth exposed to man-made or natural disasters go on to develop PTSD. It is the least common PTEs, kidnapping (0.6%), physical abuse by a caregiver (2.0%), physical assault by a romantic partner (1.3%), sexual abuse (3.8%), and rape (2.5%) that are associated with the highest rates of PTSD (range: 25.2% to 39.3%).

RISK FACTORS FOR THE DEVELOPMENT OF PTSD

Genetic Factors

As reviewed in the child abuse chapter in this text, genetic factors, in part, explain why some traumatized children go on to develop PTSD, and others do not. The genetic risk factors associated with PTSD, however, are not unique to PTSD. Nearly all genetic markers that have been reported to increase risk for PTSD following experiences of child abuse or other traumatic events have been associated with risk for a range of different psychiatric problems, as well as risk for the development of substance use disorders (9).

Trauma Characteristics

Trauma factors are among the best replicated predictors of PTSD onset, severity, and persistence. As noted above, type of trauma predicts risk for PTSD, with risk for PTSD greatest after experiences of kidnapping, physical abuse by a caregiver, physical assault by a romantic partner, sexual abuse, and rape (8). In addition, the greater the severity of the sexual (10) and physical assaults (11), the greater the likelihood of PTSD developing. Increased risk for PTSD is also associated with traumatic events that are unexpected (12) and chronic (13,14), and when the victim is in close emotional and physical proximity to the event (15). Polyvictimization is another factor that adds to the severity and complexity of trauma symptoms (16).

Posttrauma Factors

Factors in the posttrauma environment contribute most in determining the likelihood of PTSD becoming chronic. The absence of social supports and exposure to ongoing psychosocial adversity are the most potent predictors of PTSD chronicity (15,17,18). Low parental support and a hostile and coercive parenting style, as perceived by children, are also potent predictors of PTSD severity (19). Enhancing the caregiver response and capacity to support the child posttrauma, is therefore an important

component of prevention and treatment interventions following traumatic experiences.

ASSESSMENT OF TRAUMA EXPERIENCES

It is best to assess children's trauma experiences utilizing information from multiple informants (e.g., parent, children, child protective service workers) (20–22). As reviewed elsewhere (23), several rating scales have been developed to assess abuse, neglect, and other traumatic experiences in children and adolescents. The Childhood Trauma Questionnaire (24) provides an excellent self-report assessment of a range of maltreatment experiences and can be utilized with children of age 12 and above. The UCLA Posttraumatic Stress Disorder Reaction Index (UCLA-PTSD-RI) is one of the most widely used trauma symptom assessment scales and includes a survey of maltreatment- and nonmaltreatment-related traumatic events (25). The PTSD-RI can be downloaded at no cost with administration and scoring instructions from the National Child Traumatic Stress Network (NCTSN) website (http://www.nctsn.org/nctsn_assets/pdfs/mediasite/ptsd-training.pdf). The Structured Trauma-Related Experiences and Symptoms Screener (STRESS) is a relatively new computer-administered measure with excellent psychometric properties (26).

TRAUMA SYMPTOM ASSESSMENT

In our clinical and research practice, we aim to have trauma history data from multiple informants prior to assessing psychiatric symptomatology in children. We then query them about various trauma experiences. If children deny a trauma we know they have experienced via other sources, we consider that evidence of "avoidance." We then let them know what we learned about from the other source, let them know that we are not going to ask them too much about those experiences at the time of the evaluation, and just want to know if they have any problems that many other children experience who have been through the type of things they experienced. We then query them regarding the presence of PTSD symptoms. If children are particularly reticent to talk, we begin by asking the more benign hyperarousal items (sleep difficulties, concentration problems, and irritability), progress to ask about the negative cognition and mood and avoidance symptoms, and then query about the more stressful reexperiencing items.

If children are living in foster care or with other guardians who do not know them well, obtaining adjunctive information from birth parents and/or school teachers can be enormously helpful. In addition, parents and caretakers are notoriously poor at identifying internalizing (depression, anxiety) symptoms. Children are the best informants of these symptoms. Children are also frequently the best to ask about

nightmares and sleeping difficulties. As traumatized children frequently have not received comfort when distressed, many do not seek adult reassurance when they wake up from a nightmare. Rather, they stay in their beds alone, terrified. Their guardians have no idea they are not sleeping through the night.

There are several well-validated trauma symptom rating scales (23), including: the UCLA PTSD-RI (27) discussed previously, Trauma Symptom Checklist for Young Children (28), Trauma Symptom Checklist for Children (29), Child Dissociative Checklist (30), Adolescent Dissociative Experiences Scale (31), and Child Sexual Behavior Inventory (32). There are also several story-based/cartoon measures available, including the Darryl (33), Andy/Angie Cartoon Trauma Scales (34), and the Levonn Cartoon-Based Interview for Assessing Children's Distress (35). Trauma-related symptomatology is also well assessed using semistructured diagnostic interviews for young (36) and school-age children (37).

PSYCHIATRIC COMORBIDITY AND DIFFERENTIAL DIAGNOSIS

Approximately three-quarters of individuals with PTSD experience one or more comorbid lifetime diagnoses, and 37% to 48% report a lifetime history of major depression (38–40). In one-half to three-quarters of all cases, the onset of PTSD is primary. The risk for major depressive disorder (MDD) following PTSD is about the same as the risk of MDD following any other anxiety disorder, and 30% to 40% more likely in individuals with a history of a pre-existing anxiety disorder. PTSD is also highly comorbid with alcohol and substance abuse disorders in adolescents and adults (41–43), highlighting the importance of routine screening for substance use disorders in youth with significant trauma histories.

The diagnosis of PTSD has numerous symptoms in common with multiple other childhood psychiatric diagnoses. In the DSM-5, PTSD and MDD have five symptoms in common. Concentration difficulties associated with PTSD are frequently misattributed to attention deficit hyperactivity disorder (ADHD) (44), and extreme irritability reported in PTSD is sometimes misattributed to mania or oppositional defiant disorder (ODD).

Determining the presence of PTSD and potential comorbid diagnoses requires careful assessment of the developmental timing of the onset of symptoms, evaluating the pattern of problem behaviors, the severity of difficulties across different settings, and the association of problem behaviors with trauma triggers. For the diagnosis of PTSD to be given, there must be at least one reexperiencing symptom, a cardinal feature of the disorder. For comorbid MDD to be diagnosed, beyond symptoms that overlap with the diagnosis of PTSD, there should ideally be at least one symptom that is uniquely associated with MDD (appetite disturbance, low self-esteem, and suicidality). For concentration problems to be attributed to ADHD, they should have

been evident before the trauma, be relatively chronic, and generally worse in a school setting. If they emerged after the trauma and are worse in the home setting or when the child is exposed to trauma triggers, they are likely not related to ADHD. Irritability is a totally nonspecific symptom associated with many of the major childhood psychiatric diagnoses. Most symptoms of ODD involve some expression of irritability, but for a comorbid ODD diagnosis to be given there should be evidence of marked and persistent defiance, disrespect, or vindictiveness. In PTSD, irritability is frequently worse when the child is exposed to trauma triggers and less evident in nonemotionally charged environments. Sleep disturbance is another symptom shared by several child diagnoses. While both PTSD and mania are associated with sleep disturbances, decreased need for sleep is the cardinal feature of mania, and nightmares and insomnia—wanting to sleep, but not being able to—are the sine qua non of PTSD.

When psychotic-like symptoms are present, differentiating between PTSD, mood disorders with psychotic features, or a primary psychotic disorder has extremely important treatment implications. A number of distinctive features of psychotic-like symptoms in traumatized children facilitate this differential diagnosis. For example, hallucinations in maltreated children are frequently trauma related, such as hearing the perpetrator's voice, or as depicted in the case example at the beginning of this chapter, are frequently illusory experiences related to safety. They are also often nocturnal (30), and frequently resolve with psychotherapeutic intervention, cessation of the trauma, and safety reassurances (45). In addition, the presence of hallucinations in traumatized children is not typically associated with other psychotic symptoms that would suggest schizophrenia or another primary psychotic diagnosis. They are less likely to be associated with negative symptoms (withdrawn behavior, blunted affect) or abnormal early development as would be typical in childhood-onset schizophrenia (46). Hallucinations in traumatized children tend to be associated with impulsive, aggressive, and self-injurious behavior, nightmares, and trance-like states, and less likely to be associated with evidence of formal thought disorder (47).

COURSE AND TRAJECTORY

Bonanno et al. (13) describe four typical trajectories that have been found in a variety of studies among individuals with different types of traumatic experiences: resilient, delayed, recovered, and chronic. The majority of individuals who experience trauma, from 35% to 65% of those exposed, tend to be in the resilient category, showing healthy functioning even shortly after the traumatic event that is maintained over time. The delayed course, comprising approximately 0% to 15% of cases, appears to show subclinical adjustment problems that increase in severity over time. Those who can be termed recovered, making up roughly 15% to 25% of

cases, show significant symptoms early on, which resolve to a large degree over time and with treatment. Those in the chronic distress category, estimated at 5% to 30% of exposed individuals, show serious symptoms and functional limitations that are resistant to treatment.

PREVENTION

There is no clear evidence supporting the use of psychological debriefing approaches posttrauma (48,49). Traditionally conceived, psychological debriefing is delivered in the early aftermath of an event in a single group session in which survivors share their experiences and reactions and reconstruct the event. Methodologic limitations restrict the conclusions that can be drawn from the available empirical evidence, but most studies show no clear benefit with debriefing interventions, and some studies in adults reported worse outcomes among individuals participating in the debriefing intervention.

The NCTSN developed a trauma-informed modular approach to psychological first aid (PFA) for use by mental health responders in diverse settings under diverse conditions which is available on the NCTSN website (http://www.nctsn.org/content/psychological-first-aid). The PFA intervention involves providing for the basic safety and comfort of survivors, connecting survivors with social supports and practical assistance, psychoeducation about typical trauma responses, tips for helping children cope, and teaching basic relaxation techniques. The PFA intervention, however, has yet to undergo rigorous evaluation (49,50).

The Child and Family Traumatic Stress Intervention (CFTSI) is a four-session prevention protocol developed for children within 30 days of a PTE (51). The central goals are to increase parent–child communication about feelings, symptoms, and behaviors related to the PTE, and to provide behavioral coping skills to the child and caregiver. The child and caregiver are separately provided psychoeducation about trauma and coping and then brought together in the final session to facilitate mutual communication and use of the skills imparted in the intervention. In an initial randomized controlled trial comparing the effectiveness of this preventive intervention to four nondirective support sessions, 3 months posttreatment CFTSI was associated with significantly lower rates of PTSD diagnoses and fewer PTSD and other trauma symptoms in the children (51).

There are currently no strongly supported pharmacologic approaches to prevent the development of PTSD posttrauma exposure. An early pilot study supported the use of propranolol (52), but a meta-analyses of studies conducted in adults suggest propranolol treatment after a traumatic event does not alter the incidence of PTSD (53). Consistent with the results of the meta-analysis of adult studies, a randomized controlled trial with 29 youth likewise failed to show an advantage of propranolol

over placebo in preventing the onset of PTSD posttrauma exposure (54). For child burn victims, there is some suggestion that enhanced pain management with morphine treatment is associated with lower rates of PTSD (55), and one small open treatment trial of three physically abused preschool-age children diagnosed with ASD secondary to serious burns that reported significant improvement in symptoms with risperidone treatment (56).

PSYCHOSOCIAL TREATMENTS

Since its inception in 2000, the NCTSN has had a far-reaching impact on extending understanding and treatment of childhood trauma in the United States. The mission of the NCTSN is to raise the standard of care and increase access to evidence-based trauma-informed interventions. Clinicians, families, and other interested parties can access a wealth of information through the website www.nctsn.org. NCTSN provides education to a wide range of audiences, from children and families to clinicians, educators, first responders, and others. Continuing education about various types of trauma, their effects, special populations, evidence-based treatments, and assessment tools is available both on the website and through webinars and in-person venues.

Trauma-Focused Cognitive Behavior Therapy (TF-CBT) is the psychotherapeutic intervention with the strongest empirical support for PTSD and other trauma-related symptoms in children and adolescents (25,57–59). TF-CBT is a 12-to-16-session intervention that was designed for children aged 3 to 18 years to reduce PTSD symptoms and other behavioral and emotional problems associated with child trauma exposure. The central components of TF-CBT are represented by the PRACTICE acronym. The "P" stands for psychoeducation (e.g., educating children and parents about the prevalence of the type of traumatic event the child experienced and common trauma reactions) and parenting skills training (parent management principles). "R" stands for relaxation skills; "A" for affective modulation skills (e.g., feeling identification; self-regulation skills); "C" for cognitive coping and processing (e.g., recognizing relations among thoughts, feelings, and behaviors); "T" for the trauma narrative (creating a narrative of the child's traumatic experiences); "I" for in vivo mastery of trauma reminders; "C" for conjoint child–parent sessions (joint sessions in which the child shares the trauma narrative with parents and other family issues are addressed); and "E" for enhancing future safety and development (25).

TF-CBT training can be obtained via attending workshops conducted by certified trainers, reviewing published treatment manuals (58,60,61), and completing a web-based training available at www.musc.edu/tfcbt. Extant data suggest the model is implemented with the strongest fidelity when the web-based training and two-day in-person workshop are completed and augmented with follow-up consultation (62).

As reviewed elsewhere (25,59), the efficacy of TF-CBT has been demonstrated in over a dozen randomized controlled trials and has been deemed "supported and

efficacious” based on current standards. Among the currently available evidence-based child trauma treatments, TF-CBT alone has been evaluated across the child and adolescent developmental spectrum (3 to 18 years), for multiple index traumas (e.g., sexual abuse, commercial sexual exploitation, domestic violence, disaster, war, traumatic grief, and multiple and complex trauma), in different settings (e.g., clinics, foster care, community domestic violence center, refugee nongovernmental organization, juvenile detention centers, human immunodeficiency virus treatment centers), in group- and individual-administered formats, in multiple countries and cultures (e.g., United States, Native American, Africa, Europe, Australia), and with both mental health and nonmental health providers (59). In all of these studies, TF-CBT has been found to be superior to the comparison conditions for improving PTSD symptoms and diagnosis, as well as other related outcomes including, depression, internalizing symptoms, externalizing problems, anxiety ratings, sexualized behaviors, relationship difficulties, and adaptive functioning (59). Moreover, the therapeutic effects of TF-CBT have been shown to be maintained over 6, 12, and 24 months following treatment (63,64).

Child–Parent Psychotherapy (65) and the Attachment Biobehavioral Catch-up intervention (66,67) represent two trauma-focused treatment models that have been developed for working with infants, toddlers, and preschoolers. For an updated list of empirically supported treatments and promising practices the interested reader is referred to the NCTSN website (http://www.nctsnet.org/resources/audiences/parents-caregivers/treatments-that-work) and a recent review by Barth et al. (68).

PSYCHOPHARMACOLOGY

Trauma-focused psychotherapies are considered the first line of treatment for PTSD in children and adolescents (25), and as of the writing of this book, there were no Federal Drug Administration (FDA) approved pharmacologic treatments for youth with PTSD. While studies of pharmacologic treatment of PTSD have demonstrated the efficacy of selective serotonin reuptake inhibitors (SSRI’s) in adults (69), support for SSRIs in children and adolescents with PTSD is lacking (70). Two randomized controlled studies examined the use of sertraline to treat childhood PTSD and both reported no advantage for SSRI medications over placebo (71,72).

Overall there is a paucity of data to guide the pharmacologic treatment of youth with PTSD. In small-scale open treatment trials with samples ranging in size from 3 to 19 youth, benefits in treating PTSD have been suggested with quetiapine (73), clonidine (74), and guanfacine (75). In a B-A-B off-on-off design, propranolol was also shown to reduce reexperiencing and hyperarousal symptoms in a study with 11 youth (76), and in secondary analyses of data from 12 youth with comorbid PTSD who were part of a double-blind, randomized controlled trial of two doses of

divalproex sodium treatment in boys with conduct disorder, those assigned to the high-dose condition of divalproex sodium had a greater reduction in PTSD symptoms than youth assigned the lower dose (77).

Glutamate N-methyl-d-aspartic acid (NMDA) receptors have been shown to be involved in fear extinction, and although the findings have been mixed, there are data showing that D-cycloserine (DCS), a partial NMDA agonist, can enhance fear extinction and the efficacy of cognitive behavioral and exposure-based therapies for PTSD in adults and a range of anxiety disorders in children, adolescents, and adults (78). In the one DCS trial completed with youth with PTSD, 57 children and adolescents were randomized to DCS or placebo plus CBT exposure-based treatment. The authors reported a trend toward DCS speeding PTSD symptom recovery during the exposure-based sessions, and evidence that the CBT and DCS group better maintained clinical gains 3 months after treatment than the CBT plus placebo group (79).

While trauma-focused psychotherapies are considered the first line of treatment for PTSD in children and adolescents (25), it is estimated that approximately 20% of youth who complete a course of TF-CBT will still meet diagnostic criteria for PTSD posttreatment (80). Further research is needed to identify pharmacologic agents effective in the treatment of PTSD, and the augmentation of evidence-based psychotherapies. Preclinical and early clinical studies in adults suggest the utility of several potential novel agents, including nabilone, norbinaltorphimine, 7,8-dihydroxyflavone, and oxytocin (OT) to target cannabinoids, opioids, brain-derived neurotrophic factor, and the OT receptor systems, respectively (81). To date, pharmacologic treatment choice for children with PTSD is best guided by the comorbid diagnostic profile of the child, and ideally used to augment evidence-based psychotherapy approaches.

CONCLUSIONS

The child trauma field has made considerable advances in recent years, promoted in large part by the efforts of the NCTSN. Trauma exposure among children and adolescents is a common phenomenon that leads to PTSD and other mental health symptoms in a significant proportion of cases. While most children show a degree of resilience in response to traumatic events, those exposed to interpersonal violence and polytraumatization are at greatest risk for ongoing distress and compromised functioning. Good trauma-informed care requires an understanding of the factors that modify outcome, thorough multi-informant assessment, and evidence-based therapy in combination with psychopharmacologic treatment when clinically indicated.

CHAPTER 5.15.3 ■ REACTIVE ATTACHMENT DISORDER AND DISINHIBITED SOCIAL ENGAGEMENT DISORDER

MARY MARGARET GLEASON AND CHARLES H. ZEANAH

INTRODUCTION

Since the mid-20th century, psychiatric literature has included descriptions of the negative impact of severe emotional deprivation (1). Descriptive studies of young children raised in institutions have consistently described abnormalities in social and emotional development in children raised in extreme caregiving adversity. Although disorders of attachment were not described in formal nosologies until the DSM-III (2), attachment theory has been the focus of active investigation for decades beginning with Bowlby (3,4). Bowlby proposed that infants are born with a biologic predisposition to develop an attachment relationship with a small number of caregiving adults from whom the child seeks comfort, nurturance, support, and protection (Table 5.15.3.1).

DEVELOPMENTAL STAGES OF THE ATTACHMENT RELATIONSHIP

In the first 2 months of life, infants preferentially orient to people's movement, faces, sounds, although they do not discriminate among people, except in very subtle ways. From ages 2 to 7 months, children become more socially interactive and appear to respond differentially to their caregivers, although they continue to socially engage with unfamiliar adults as well. Focused attachment behavior, characterized by proximity seeking in times of stress, appears around 7 to 9 months of age, heralded by the onset of separation protest and stranger anxiety. According to attachment theory, the attachment system works in conjunction with a number of other biologically driven systems, most prominently the exploration system. An equilibrium develops between the attachment and exploration systems. The parent serves as a secure base from which the child can explore the world when the exploration system is more highly activated, and a safe haven to whom she/he can return in times of stress when the attachment behaviors are more prominent.

Interactions of Attachment, Exploration, and Social Systems

In human infants, attachment formation appears to be an example of experience-

expectant neural development, by which infants are hardwired to form selective attachments to caregiving adults. Environmental and relationship factors play a strong role in the type of attachment relationship that the child develops. Ainsworth demonstrated a relationship between early patterns of parental, sensitivity, and infant responsiveness, and the development of a secure attachment relationship at age 12 months (5,6).

Patterns of attachment serve as risk and protective factors for subsequent psychosocial adaptation. Children with insecure attachment patterns are at higher risk for subsequent psychiatric disorders and impairment from emotional and behavioral symptoms than securely attached infants (7,8).

TABLE 5.15.3.1

DEVELOPMENT OF ATTACHMENT

	0–2 Months	2–7 Months	7–18 Months	18–26 Mon

Disorders of Attachment

Definitions of the categorical disorders related to attachment patterns have evolved over the last decades, with different nomenclature, but with fairly consistent core features. For the first time in the DSM-III-R, the two subtypes of "inhibited" and "disinhibited" reactive attachment disorder were introduced; these distinctions

remain in all extant nosologies.

The ICD-10, which preceded the DSM-5 and is used primarily in Europe, similarly describes two separate disorders, both with an emphasis on social relatedness. The first is simply “reactive attachment disorder of childhood” and describes children with inhibited emotional responsiveness and contradictory social responses. In the ICD-10 nosology, “disinhibited attachment disorder of childhood” describes children with diffuse attachments and indiscriminate behaviors (9).

For the purposes of this chapter, the DSM-5 classifications will be used. The DSM-5, published in 2013, also describes two distinct disorders in place of what was previously called reactive attachment disorder (RAD) (10). In the DSM-5, the disorders are called RAD and disinhibited social engagement disorder (DSED). These two disorders are explicitly linked to observable patterns of attachment-related behaviors and to a child’s lack of adaptive use of the primary attachment figure. Both require “insufficient care” and provide specific examples that may increase the risk of the disorders, highlighting the importance that social and emotional neglect play in the development of both disorders (11).

In the DSM-5, both sets of criteria require a developmental age of at least 9 months to ensure that the child has the potential to have developed a focused attachment relationship. Both disorders also require pervasive, rather than relationship-specific patterns. However, beyond these commonalities, the two disorders have distinct clinical presentations as well as different patterns of associated features, different trajectories, and strikingly different responses to intervention (12,13).

Phenomenology of RAD and DSED

Reactive Attachment Disorder

In RAD, children show restriction of affect and behavior in situations that would normally activate the attachment system. In a healthy attachment behavioral system, stressors activate the attachment system and a child seeks comfort from his or her attachment figure. Children with RAD demonstrate a consistent pattern of inhibition or emotional withdrawal around adult caregivers as well as significant negative emotional regulation and limited reciprocity. Specifically, children with RAD do not seek comfort from an attachment figure when distressed and are not calmed when comfort is offered. The difficulties in social or affective interactions may present with minimal social or emotional responsiveness to other people, a lack of positive affect and periods of sadness, distress, or irritability that does not seem to be related to typical triggers. Although some of these features may be seen in children with other disorders, it is their presentation in the context of a lack of attachment patterns that makes the criteria specific and the disorder distinguishable from other disorders

(14).

Disinhibited Social Engagement Disorder

In DSED, children exhibit pervasive social disinhibition. In novel situations, these children are overly familiar with strangers. They do not demonstrate social reticence when meeting new adults, they tend not to check back with a caregiver in new situations, and caregivers report the child might go off with a stranger (10). Preschool children may exhibit verbal in addition to physical intrusiveness, by asking overly personal questions with unfamiliar adults. These behaviors are often experienced by others as intrusive and excessive rather than social or friendly (15).

Other Areas of Clinical Concern

Comorbid RAD and DSED. The DSM-5 does not preclude concurrent RAD and DSED. A number of studies of maltreated and institutionalized children, have revealed modest intercorrelations between signs of RAD and DSED, but no association among categorical diagnoses in children with a history of institutional care (12,14,16). However, in a large study of children ages 26 to 89 months in the Netherlands, 15% of children in therapeutic foster care and 3% of children in typical foster care met criteria for both inhibited RAD and DSED (17). Importantly, the mixed pattern was associated with more internalizing and externalizing problems than the single diagnosis, suggesting distinct groups or a higher level of severity. However, the clinical presentation of these children is not clear and it is possible that they present with apparent indiscriminate behaviors because of passivity of RAD rather than pervasive disinhibition.

Relationship Disorders. Although RAD and DSED occur within the context of insufficient caregiving, they do not indicate a relationship specific disorder. Some parent–child relationships may not function in a way that supports a child's development adequately, resulting in problems in the relationship between a caregiver and a child, rather than the patterns specific to the child. Disorders of relationships may present as severely disordered attachment behavior within the context of a relationship, revealed by the child's distorted use of the caregiver as an emotional secure base (18,19). Four major types of these disorders were described: role-reversed behaviors, provocative self-endangering behaviors, excessive clinginess and restriction in exploration, and excessive vigilance and hypercompliance. These relationship classifications have been shown to be associated with less adaptive relationship qualities and have proven interrater reliability (19). Moreover, they have not been well studied and have limited established validity. The *DC: 0–5* includes a categorical disorder, "Relationship Specific Disorder of Early Childhood," that would subsume the previously described

attachment relationship disorders (20).

Associated Clinical Features

The particular risks and contexts that give rise to RAD and DSED also have been associated with other clinical conditions. The differences in these clinical correlates support the distinction of RAD and DSED as separate disorders.

Clinical Correlates of RAD. RAD has been shown to be associated with atypical patterns and incomplete development of attachment, developmental delays, depressive symptoms, and a quasiautistic clinical presentation. Attachment classifications and security are consistently associated with RAD. In the Bucharest Early Intervention Project (BEIP), a randomized controlled trial of foster care as an intervention for children exposed to institutional care, both attachment and RAD were examined concurrently (21). In this study, the signs of RAD were inversely associated with the degree of attachment formed, with the highest level of RAD in children classified as unclassifiable (22). In longitudinal follow-up, the association between low attachment security and signs of RAD was evident throughout the preschool years (14).

Developmental delays are modestly associated with signs of RAD (14). This association likely stems from the shared risk factor of caregiving adversity, rather than a causal association between RAD and developmental delays.

Signs of RAD are associated with signs of depression, which shares a presentation of limited positive affect and negative emotionality. However, in the BEIP, fewer than half of children with RAD met full criteria for major depressive disorder at 54-month follow-up, suggesting that the disorders themselves are distinct (14).

Rutter et al. (23,24) described a small subgroup of previously institutionalized children who presented with “quasiautistic” features, including limited social reciprocity, poor observance of social boundaries, and poor social awareness. These children, who represented 9.2% of previously institutionalized children, demonstrated several features that distinguished them from typically described autism, including a normal or small head circumference, association of quasiautistic feature severity with duration of institutionalization, and a reduction in quasiautistic features over a course of 2 years following adoption.

Clinical Correlates of DSED. The association between DSED and attachment is less clear than that of RAD. In a study of high-risk infants, Lyons-Ruth (25) demonstrated a higher level of indiscriminate behaviors associated with disorganized attachment (compared to organized) patterns and with insecure (compared with secure) attachment patterns in the strange situation. In the English and Romanian Adoption Study (ERA), Rutter et al. (26) also reported that children adopted from Romania to

the United Kingdom between 6 and 42 months with no signs of disinhibition had higher rates of secure attachment (79%) compared to those who had some disinhibition (53.4%). On the other hand, the association between signs of DSED and attachment has been examined in diverse samples, with most studies indicating a modest inverse association with attachment security. Consistently, a few children exhibit both secure attachments and signs of DSED (26–29). Some have argued that if children with DSED can have a secure attachment relationship, that the disorder does not represent a core deficit of an attachment problem (11) whereas others suggest that the associations with attachment indicate that attachment theory provides a parsimonious way of understanding the outcomes related to signs of DSED (30). Because of the centrality of child-caregiving relationships in early life, there is certainly no question that attachment plays an important part in most areas of development in children exposed to adversity.

Others have explored other possible core deficits to explain socially indiscriminate behavior in children exposed to adversity. In the BEIP, cognitive impulsivity (inhibitory control deficits) as measured by the Bear Dragon task (a research variant of "Simon Says") was only modestly associated with levels of signs of DSED, suggesting that cognitive inhibitory control also does not fully explain DSED. Others have explored whether DSED is associated with a deficit in theory of mind or an exaggerated hostile attribution bias, neither of which explained the variability in signs of DSED (31).

Biologic underpinnings of DSED have also been explored. In a study of 4 to 17 year olds with a history of institutional care compared with noninstitutionalized children, higher levels of indiscriminate social behaviors were associated with lesser differentiation in amygdala activation on functional MRI between mother and stranger faces in institutionalized compared to noninstitutionalized children (32). The finding suggests that indiscriminate behavior is associated with a neurodevelopmental lack of discrimination, although caution is warranted in extrapolating from studies of school-age children to younger children. Similarly, indiscriminate social behaviors have also been linked to abnormal cortisol secretion patterns in children with the most severe growth restriction after institutional care (33). Lastly, Drury et al. who studied functional polymorphisms in brain-derived neurotrophic factor (BDNF) and the serotonin transporter (5httlpr) on levels of indiscriminate behavior over time in the BEIP sample. They found that those children who were short/short 5-httlpr or the met 66 BDNF allele carriers—thought to be most associated with responsivity to environment—demonstrated the lowest levels of indiscriminate behavior in children in foster care and the highest levels in the care as usual group (34). These findings highlight the complex interactions between genes and susceptibility to adverse or advantageous environments with respect to indiscriminate social behaviors.

Indiscriminate behavior has also been noted to be accompanied by hyperactivity

and inattention. While these symptoms are not part of DSED, some have suggested that the inattention and overactivity seen in children with a history of institutionalization and attachment disturbances may reflect an "institutional deprivation syndrome" (12). Rather than invoking traditional attention deficit hyperactivity disorder (ADHD), these investigators suggest this syndrome is directly related to institutional experience, citing correlations between hyperactivity and attachment disturbances and duration of institutional care. In the BEIP, there was no association between caregiver-reported signs of DSED at 24, 30, or 42 months and activity, but a strong association at 54 months with signs of ADHD (14). However, discriminant validity was demonstrated as only 25% of the children who met criteria for DSED also met DSM-IV criteria for ADHD.

Epidemiology

Although believed by most to be a rare disorder, RAD has not been included in population-based studies, and the actual prevalence is unknown. Interpretation of estimates in other groups must be limited because of varying application of diagnostic criteria. Nevertheless, experts agree that the disorder is rare in the general population (22).

Rates of RAD in high-risk samples have been studied slightly more extensively, but some of the studies used outdated diagnostic criteria and combined the inhibited and disinhibited forms. Taken together, rates range from 1% to 20%, in a range of settings (19,35,36). These differences likely reflect differences in referral patterns and method of diagnosis. In a large cohort study that applied rigorous diagnostic classifications, 1% of children met ICD-10 criteria for RAD (37). In a study of 10- to 47-month-old maltreated children in US foster care, 35% of children met criteria for RAD, with an additional 17% who met criteria both for RAD and DAD (the ICD-10 disorder that parallels DSED) (38). In the BEIP, rates of RAD in the longitudinal sample of children with a history of institutional care were under 5% at four time points from mean age of 22 months baseline to 54 months, with rates higher among children randomized to care as usual rather than those randomized to foster care (14).

Rates of DSED are higher than RAD. In the US maltreated toddlers, 22% met criteria for the ICD-10 diagnosis that parallels DSED, with an additional 17% who met criteria for both forms of the disorders (38). In the BEIP, rates of DSED in the longitudinal sample of children with a history of institutional care were 31.8%, 17.9%, 18.0%, and 17.6% at baseline before randomization (mean age 22 months), 30, 42, and 54 months, respectively (14).

Etiology

Insufficient care is required as a criterion in the diagnoses of RAD and DSED in the

DSM-5 and strongly recommended in ICD-10 for the parallel disorders. This caregiving may include social neglect or deprivation, changes in caregivers that limit opportunities to form stable attachments, such as multiple caregiving disruptions in foster placements, or atypical caregiving environments such as institutions, that provide structural impediments to forming selective attachments (10). The DSM-5 criteria further state that the care is thought to contribute to the behaviors noted in both RAD and DSED.

Although it can be difficult to confirm early adversity if a child's early experiences are not known, this criterion ensures that children with either social inhibition or social disinhibition without a known history of caregiving adversity are not diagnosed with either disorder. This is particularly important because children who have experienced excellent caregiving but a microdeletion on chromosome 7 (i.e., Williams syndrome) show indiscriminate behavior that is similar to the patterns in DSED (39). To date, no studies have examined the phenomenology of indiscriminate behavior in the two conditions to determine if they are clinically distinguishable.

There is evidence to support a dose-dependent effect of insufficient care on attachment behavior disturbances. Romanian toddlers on a pilot institution unit with a higher staff ratio and staffing schedules more conducive to the development of attachment relationships had lower rates of indiscriminate behaviors than those in the traditional unit, and higher rates than children who had never been institutionalized (40). Within standard institutional care, children who received higher-quality caregiving also were more likely to have lower rates of disturbed attachment behaviors (22). After adoption, the same dose-dependent relationship has been documented, with length of institutionalization correlating closely with the severity of indiscriminant attachment disorder behaviors (15,41). In the United States, rates of RAD parallel the environmental or family risk of adverse caregiving. Children in foster care had the highest rates of RAD, followed by homeless children and then children in Head Start (42). A number of studies have demonstrated an association between length of institutional care and level of indiscriminate behavior in children adopted internationally. Rutter et al. (26) reported that 8.9% children who had been adopted before age 6 months showed marked disinhibition, compared with 26% of those adopted between 6 months and 42 months showed the same level of disinhibition. The association between social disinhibition and duration of institutional exposure persisted at follow-up at age 11.

It should be emphasized that most children exposed to maltreatment or institutionalization do not develop DSED (26). While the protective mechanisms are not yet sufficiently understood, being considered a "favorite child" may be one factor favoring a resilient outcome to young children in institutions (22). It is likely that dose of exposure to institutional care, quality of care within that institution, and a child's biologic and genetic make-up influence the development and persistence of

signs of DSED. Very early life experiences, which are almost impossible to measure systematically in children who are placed in institutional or other adverse care, likely also contribute to the outcomes. For example, in the BEIP, the sole independent predictor of signs of DSED at 54 months was the degree of disorganization of attachment behaviors in the strange situation at the baseline data point (mean of 22 months), suggesting that very early caregiving may put a child at risk for persistent signs of DSED (14).

Diagnosis

Clinical History and Interview

As with all other psychiatric disorders in young children, evaluation of a child who may have RAD is a multimodal process that should involve more than one appointment, ideally in more than one setting. Interviews with caregivers as well as child–caregiver observations provide the central core of the diagnostic evaluation. An interview reviewing RAD and DSED should address a child's attachment behavior with the primary caregiver, including the presence of a focused attachment relationship, inhibited or indiscriminate patterns, as well as patterns of secure base distortions.

First, the presence of a focused attachment relationship should be explored. Specifically, an interviewer should assess whether the child has one adult (or more) from whom he or she seeks comfort, reassurance and nurturing, particularly in times of distress. In addition, patterns of inhibited attachment behaviors (not using attachment figure for comfort), and indiscriminate attachment behaviors should be identified. It is also useful to assess the child's use of caregiver as a secure emotional base and to explore distortions of this secure base (43). Relationship-specific patterns of behaviors and interaction patterns are also important to establish. The use of a semistructured interview, such as the Disturbances of Attachment Interview (44), may be helpful to assess these categories of RAD and DSED behaviors in a systematic manner.

The context of the child's attachment behaviors and relationships must be investigated during the interview, including details of a child's caregiving. To meet criteria for RAD and DSED, insufficient caregiving must be established. Details of the caregiving history, with attention to neglect, changes in caregiving relationships, significant losses, or institutional care should be investigated during the interview. It should be noted that for some children who have experienced adversity, the information about past caregiving is not available or that elements of current adversity may not be disclosed in early assessments. Thus, a low threshold for considering these disorders should be maintained when a clinician notes the clinical syndromes.

Because of the high rates of other psychiatric disorders in children with high-risk family or environmental backgrounds, reviewing other areas of disturbance is an essential part of the history. Disruptive behavior disorders, mood disorders, and anxiety disorders are seen at higher rates in maltreated populations. With any child, but particularly one whose history includes a deprived caregiving context, assessment of both developmental and cognitive status is important. In particular, a child who is not developmentally 9 months of age should not be diagnosed with RAD because he or she may not have the developmental capacity for an attachment relationship and therefore cannot have a disorder of such.

Clinical Observations

Clinical practice settings provide opportunities to observe and stimulate attachment behaviors (45). Observing children in the beginning of the assessment when first meeting the interviewer (a stranger) can provide information about how a child references and/or seeks comfort from a caregiver in the context of a new person and setting. In addition, creating a brief separation can activate the child's attachment system and provide valuable information about how a child uses the parent upon reunion. A single observation is rarely sufficient to make a diagnosis of RAD, and serial observations are recommended (45). Throughout the assessment, it is valuable to compare the child's interactions with a caregiver and the stranger. In addition, observations of a child with all important caregivers can help to distinguish between child-specific behaviors and relationship-specific behaviors (46).

Standardized observations of attachment behaviors have primarily been studied for assessment of attachment classification, a qualitatively different categorization of attachment. However, one clinical assessment of attachment involving a stranger, separations and reunions and the introduction of a robot as a mildly distressing stimulus have also been used reliably to diagnose attachment disorders in a clinical context (42). Another structured interaction procedure, the Crowell, has been used for relationship assessments, although not necessarily diagnoses, in multiple clinical settings. The procedure includes opportunities for unstructured play interactions, joy sharing with bubbles, structured tasks of increasing difficulty, and a separation and reunion procedure. The use of standardized procedure provides the clinician the opportunity to observe patterns of children's attachment behaviors in a consistent manner in repeated episodes and potentially with different caregivers, reducing the influence of other variables.

Differential Diagnosis and Comorbid Disorders

Institutionalized and maltreated children are at risk for other diagnoses related to their early experiences, and both RAD and DSED must be distinguished from these

disorders. Most prominent among them are disruptive behavior disorders, anxiety disorders, particularly posttraumatic stress disorder, and mood disorders (47–49).

The differential diagnosis of RAD is broad and includes developmental concerns as well as externalizing and internalizing problems, and neurodevelopmental concerns. A child with developmental delays who is not yet 9 months developmental age will not show the usual patterns of healthy attachment but will also have other findings consistent with developmental delay. RAD must be distinguished from oppositional defiant patterns. While both share negativistic affect and both may include noncompliance, the pattern in RAD is a passive noncompliance rather than an outright defiance seen in ODD. Children with anxiety disorders may present with an inhibited affect, but in RAD, the presentation is pervasive, whereas the inhibition related to anxiety tends to dissipate in comfortable situations. Depression should be evaluated in children with signs of RAD, as the signs of both show moderate–strong correlations as early as 22 months. Posttraumatic stress disorder shares an etiology of adversity with RAD but shows limited overlap in the clinical presentation, with the exception that dissociative patterns will cause a lack of reciprocity and both can present with negativistic emotions.

The differentiation between quasiautism described by Rutter et al., which shares some traits with RAD, and an autism spectrum disorder may be hard to assess when a child is first evaluated and this differentiation should be considered in any child with a history of caregiving adversity who is diagnosed with autism as well. In longitudinal follow-up, they will improve in a safe caregiving environment, although this differentiation is not useful when a patient is first presenting for care. While children with quasiautistic features present with behaviors similar to those of children with autism, they may be distinguished by (1) normal or small (not large) head circumference, (2) frequent (though socially inappropriate) approaches to others and even indiscriminate behavior, and (3) more use of language (24). Stereotypies can occur in children with a history of institutional care as well as those with autism spectrum disorders, so may not serve as a differentiating factor.

For children for whom DSED is considered, a range of disorders must be considered as well. Externalizing symptoms have been associated with signs of DSED, especially as children move into the later preschool and school-age years (14,50). ADHD is common among children with history of adversity, and may be associated with DSED, but the hyperactive-impulsive form can be distinguished by the pervasiveness of the impulsivity, which is not confined to social interactions. Aggressive behaviors are not associated with signs of DSED in toddlerhood and early preschool years, although there is a moderate association between disruptive behavior patterns beginning at 54 months (14,40). Mood and anxiety disorders should be considered in any child with a history of caregiving adversity. There is little phenotypical overlap between DSED and depressive disorders or anxiety disorders or of posttraumatic stress disorder, although the shared risk factor of adversity means

a full assessment of these possibly comorbid conditions is warranted.

Course and Prognosis

In a small study of young children in foster care, nearly all of the dyads showed a distinct pattern of attachment behaviors, most within days of placement, although those patterns were vulnerable to external disruptions like respite placement (51). While this study did not address a clinical diagnosis of RAD, it highlights the rapidity with which infants can develop new attachment relationships, particularly when placed in favorable caregiving settings.

At this time, prospective longitudinal studies of RAD follow children through the school-age years. The challenges of diagnosing RAD in infants and preschoolers are magnified in older children; measures of normal attachment exist but there is no gold standard as there is in early childhood. The application of the infant and preschool definitions of a disorder is likely inappropriate (45). In a study in the United Kingdom, using a single diagnosis that included both inhibited and disinhibited forms of the DSM-IV diagnosis of RAD generated by the Child Age Psychiatric Assessment interview, the diagnosis was associated with lower rates of security based on the McMaster Child Attachment Story Task (52). As in younger children, the diagnosis did not preclude a secure attachment classification, especially in girls. This study may be the beginning of more rigorous study of the constructs of RAD and DSED in older children, but unfortunately the merged diagnostic category limits its contribution. Other studies of attachment disorders in older children have used a broadly defined syndrome (called "RAD") that includes criteria included in both the inhibited syndrome of RAD and disinhibited DSED as well as sometimes signs of disruptive behavior patterns and moral deficits (53–55). To date, it is unclear how this construct relates to RAD and DSED as well as whether it describes children not currently well described in existing nosologies.

Treatment

Data related to specific interventions for RAD are limited. A commonality on which most infant mental health interventions are based, is the inclusion of both child and primary caregiver as participants in the intervention and the promotion of sensitive, responsive caregiving relationships.

Foster Care Placement

While the need to remove a child from pathologic care or the extremes of deprivation seems to be an obvious intervention for RAD, only one study has examined the effect of this process on children's attachment disorder behaviors. The BEIP, the only randomized controlled trial of foster care for children with a history of institutional

care, includes baseline data about the children before their placement into foster care. After randomization to care as usual or foster care at a mean age of 22 months, children randomized to foster care and their families received regular visits and support from social workers who were supervised by experts in infant mental health and foster care (56). At follow-up at 30, 42, 54 months and 8 years, signs of RAD in children placed in foster care were indistinguishable from community controls (13). The rate of resolution in signs of RAD is striking.

Signs of DSED decreased far more slowly than signs of RAD. Signs of DSED were higher in the care as usual group than in community controls, with children in foster care showing an intermediate level. Importantly, early placement in foster care was associated with a greater reduction in signs of DSED. These results suggest that placement in a safe, family environment is an effective intervention for inhibited attachment disorder behaviors, but is not sufficient to eliminate signs of indiscriminate attachment disorder. The relative persistence of DSED after removal from institutional care and placement in family care has been documented in other populations as well, with follow-up after intervention into adolescence (12,41,57). Clearly, more effective interventions for DSED are needed, although prevention and early intervention for maltreatment or adversity will be the most powerful approaches to reduce the impact of DSED in high-risk populations.

Attachment-based Therapies

Attachment-focused therapies have not been studied as interventions for RAD, but the enhanced foster care of the BEIP, which influenced both RAD and DSED albeit at different magnitudes, was strongly influenced by attachment theory. Given the lack of other specific treatments for RAD or DSED, there is reason to consider attachment-based interventions in this discussion. Attachment-based therapies seek, through various mechanisms and points of entry, to strengthen the primary caregiving relationship.

A number of caveats must be identified when considering attachment-based therapies in the context of RAD (58). While these attachment-based therapies assume a focused attachment relationship (albeit usually an unsatisfying one) not all children with RAD or DSED have a focused attachment relationship. It is not known whether attachment-based interventions can stimulate development of an attachment relationship where none exists.

For RAD, there is a theoretical basis for believing that interventions that strengthen the attachment relationship may create an environment in which a child's negative internal representations can be modified and which can interrupt the perpetuation of RAD, which is thought to be closely tied to attachment security (57). Particularly important may be helping the child's caregiver reinterpret the child's behaviors in order to function as a more effective secure base (59).

Given the different correlates and responsivity to family-based living, it seems

likely that RAD and DSED might require different interventions, and that DSED might be less likely to respond to an attachment-based treatment. In spite of these caveats, the BEIP findings suggest that promotion of a healthy parent–child relationship and family environment through an attachment-focused supports may have a place in a treatment plan for DSED as well as RAD.

Infant–Parent Psychotherapy. Infant–Parent Psychotherapy (IPP) and Child–Parent Psychotherapy (CPP) are therapies which draw on psychoanalytic and attachment theory to provide corrective attachment experiences to the parent and infant. In keeping with its psychodynamic roots, the development of parental insight into her use of the child as a negative transference object is defined as one target of treatment. In addition, through the therapeutic relationship and interventions, IPP provides the dyad with corrective attachment experiences that model and emphasize nurturing, support, protection, and reciprocity. The third mutative factor is described as the power of mutually satisfying interactions. IPP and CPP sessions are flexibly structured, and access a parent's current and past experiences to increase awareness and insight into the relationship. The therapist provides a nurturing, and supportive experience for both partners in the dyad. CPP shares the same foundation, but uses play as the modality through which the child and parent together can create joint meaning in their interactions (60).

IPP and CPP have been used and studied extensively with sustained positive effects on security of attachment, child trauma-related symptom and behavioral difficulties, cognitive functioning, parent trauma-related symptoms, as well as regulating cortisol release patterns (61–63).

Attachment and Biobehavioral Catch-up. Attachment and Biobehavioral Catch-Up (ABC) was developed for foster caregivers to support them in developing sensitive, nurturing, nonfrightening parenting behaviors (64). In ABC, dyadic interactions provide opportunities for psychoeducation and support in understanding the needs of infants and young children as well as caregiver state of mind. In randomized controlled trials, ABC has been associated with decreased rates of disorganized attachment status and with increased caregiver sensitivity and, notably, normalized diurnal cortisol patterns in toddlers (65–67). With the intense focus on the developing caregiver–child relationship, this model may have promise for RAD and to a lesser extent with DSED.

Circle of Security. The Circle of Security (COS) is an intervention designed to enhance attachment relationships between young children and their caregivers through psychoeducation, video review, and insight-oriented psychotherapy (68). Originally, it was disseminated as a manualized, time-limited group psychotherapy using video feedback. This intervention has since been adapted for dyadic therapy. More recently, parenting DVDs based on the model have been created; these combine

education about attachment with an opportunity for caregivers to reflect on their child's needs and the challenges each faces in meeting those needs (69). For the video therapy approach, an observational procedure including the standard SSP and the COS Interview is completed at baseline for treatment planning (70). The intervention emphasizes the sophisticated capabilities of young children and draws caregivers' attention to the meaning of subtle behaviors. It also teaches parents to recognize their own maladaptive responses and how to override them (71).

Video-based Intervention to Promote Positive Parenting. Video-based intervention to promote positive parenting (VIPP) is a brief, manualized attachment intervention delivered in four home visits to parents of infants less than 1 year of age (72). VIPP was drawn explicitly from attachment research and attempts to promote mothers' sensitive interactions with their infants. Interveners' present written materials and review videotaped infant–parent interactions during home visits. An expanded version, VIPP-R, provides an additional 3-hour home visit that focuses on the parent's childhood attachment experiences. Research has documented enhancement of sensitive and nurturing parenting behaviors, attachment disorganization, and externalizing behavior problems during preschool (73,74).

Parent Management Training Models. No intervention other than foster care has been explicitly studied as a treatment for DSED. In part, as the core deficit of this disorder is not as well understood, designing a focused treatment may be more difficult. DSED has some overlapping presentation with disruptive behavior patterns, especially in the older preschool ages, although there is no suggestion that it shares a common etiology with these problems. Parent–Child Interaction Therapy (PCIT), a parent management training approach, has been shown to reduce child disruptive behaviors as well as child internalizing problems, executive functioning, and emotional recognition skills (75–77). In maltreating families, PCIT was associated with improvement in a number of aspects of observable parent–child interactions, including more praise and use of verbal positive reinforcement as well as parental sensitivity on the Emotional Availability Scale in these high-risk families (78). Despite limitations in generalizing from this sample, a parent management training approach that increases parental sensitivity and reduces types of impulsivity may also have some promise in reducing impairment associated with DSED.

Treatments not Recommended. Perhaps because of the high intensity clinical needs of children who have experienced severe deprivation or maltreatment, alternative treatments for emotional and behavioral problems in adopted children have proliferated. Coercive treatments including holding and rebirthing have been associated with fatalities, are not supported empirically, and have been condemned by the American Academy of Child and Adolescent Psychiatry (AACAP) (45,79–82).

Summary and Future Directions

The empirical support for RAD and DSED has grown substantially in recent decades. RAD is strongly associated with incompletely developed attachment and resolves quickly after removal from adversity and placement into adequate caregiving environment. DSED, on the other hand, appears to derive from the persistence of behavioral adaptations to very early experiences rather than concurrent caregiving experiences. Despite the substantial progress in characterizing the disorders, a number of questions persist. First, we must identify the factors and interactions that put some children at risk of developing RAD or DSED or confer protection against either of these disorders. Additionally, better understanding the core deficits of each disorder will provide opportunities for focused interventions. Most importantly, prevention of both disorders can be achieved through advocacy for healthy caregiving environments for all children, especially those whose families cannot protect them. First-line intervention must include removal from an adverse caregiving environment and placement in a safe, sensitive environment. After placement in a safe caregiving environment, current treatment recommendations focus on enhancing positive caregiver interactions, although the specific modalities have not been established.

CHAPTER 5.15.4 ■ CAREGIVER-FABRICATED ILLNESS IN A CHILD

ANDREA G. ASNES

HISTORICAL NOTE, DEFINITIONAL ISSUES AND THE EVOLUTION OF A NAME

In 1951, Asher first used the eponym Munchausen syndrome to describe adults who consistently fabricate symptoms of illness for themselves, leading to numerous medical investigations and frequently to surgical operations (1). The syndrome was named after Baron von Munchausen of Hanover who lived in the 18th century and was renowned for telling greatly embellished stories about his adventures in the wars against the Turks (2). In 1976, Sneed and Bell used the term “the dauphin of Munchausen” to describe a case in which a 10-year-old boy presented with factitious recurrent urinary calculi and in which the mother was suspected of colluding with the child in fabricating the symptoms (3). The following year, Meadow coined the term “Munchausen syndrome by proxy” in his report of observations of two cases in which parents repeatedly caused their children to be ill (4). Prior to this time, there had been reports in the literature of cases referred to as “nonaccidental poisoning” in which children repeatedly presented as diagnostic dilemmas and were found to have been poisoned by a parent; such cases would today be classified as child abuse (5,6). Subsequent to Meadow’s initial report, other suggested names included Meadow syndrome or Polle syndrome, but these gave way to the still frequently used Munchausen syndrome by proxy (7–9). Other terms since used to describe this diagnostic entity have addressed the complexity inherent in making this diagnosis. These include pediatric condition falsification, caregiver fabrication of illness in a child, child abuse in a medical setting, medical child abuse, and factitious disorder by proxy. The most recent version of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) refers to factitious disorder imposed on another, and specifies that deception by the caregiver is a necessary diagnostic feature (10). The range of clinical presentations encountered in practice, however, extends well beyond this relatively narrow definition. Indeed, the diagnosis of caregiver-fabricated or induced illness in a child does not require an understanding of the perpetrator’s motive any more than a caregiver’s reasons for physically battering a child need to be known in order for a diagnosis of physical abuse to be made (10,11). The evolving name of this diagnostic entity reflects the challenge both of identifying pathologic behavior in one person (the caregiver) and not in another (the child victim), as well as in ascribing (or studiously not ascribing) a motive to the diagnosed person (12).

Initially, Meadow described a caregiver disorder in which a person persistently fabricates symptoms of illness on behalf of another, thereby causing that person to be regarded as ill (4). Meadow subsequently updated and operationalized the syndrome to include a combination of: (1) an illness fabricated in a child by a parent or someone in loco parentis; (2) persistent presentation of a child to medical care while the caregiver denies causing the child's illness; (3) the illness goes away when the child is separated from the perpetrator; and (4) the perpetrator is considered to be acting out of a need to assume the sick role by proxy or as another form of attention-seeking behavior (13). In 1998, a multidisciplinary group convened by the American Professional Society on the Abuse of Children developed definitional guidelines which have since been refined (14,15). These guidelines define the disorder as encapsulating two distinct entities: the maltreatment of a child and the motivation of the adult who perpetrates the maltreatment. The term "pediatric condition falsification" is employed to describe the form of child abuse in which an adult fabricates or directly causes symptoms and/or signs of illness in a child, resulting in a perception of that child as sick (15). The severity of the disorder and extent of the fabrication are variable. In the least severe cases caregivers only report false symptoms, and the physical harm to the children is only that resulting from the unnecessary medical investigations carried out in attempting to diagnose the illnesses. At the other end of the spectrum are instances in which caregivers have caused severe physical harm to or even the death of their children in the continued pursuit of making their children appear ill. Roesler and Jenny emphasize the importance and necessity of singling out the maltreatment of a child in making a diagnosis of what they termed "medical child abuse," particularly for pediatric providers (16). These authors illuminate both the need to diagnose the child with abuse and the lack of necessity to diagnose the caregiver/perpetrator with anything at all. Pediatric providers need not know the motivation of the perpetrators of child abuse in order to diagnose abuse, and attempting to identify such motivation (and, therefore, ascribing a psychiatric diagnosis) is beyond the scope of pediatric expertise. The American Academy of Pediatrics Committee on Child Abuse and Neglect in 2013 settled on the term "caregiver-fabricated illness in a child" and noted that in the setting of multiple definitions and diagnostic terms to describe this form of maltreatment, the essential feature is the "caregiver's falsification and/or inducement of physical or psychological symptoms or signs in a child" (17). The DSM-5 identifies the diagnosis of factitious disorder imposed on another (previously factitious disorder by proxy) and lists the diagnostic criteria as:

A. Falsification of physical or psychological signs or symptoms, or induction of injury or disease, in another, associated with identified deception.
B. The individual presents another individual (victim) to others as ill, impaired, or injured.
C. The deceptive behavior is evident even in the absence of obvious external

rewards.

D. The behavior is not better explained by another mental disorder, such as delusional disorder or another psychotic disorder (10).

Notably, this definition excludes caregiver fabrication of or imposition of illness on another for reasons of secondary gain. Caretakers, for example, may invent or induce illness in children to keep them from attending school or falsely allege sexual abuse as a tool in custody battles. In other forms of pediatric condition falsification, the parent falsifies the illness solely to gain help with other problems, such as depression (18). This latter form has been dubbed as “help seeking” and is exemplified by the mother who puts cranberry juice in a child’s diaper as a reason to be seen by a doctor, but the behavior ceases once the mother’s own psychological needs have been identified and treated (18). Caregivers who abuse a child physically and then invent an organic medical ailment to explain the abuse would not, therefore, be diagnosed with factitious disorder imposed on another, nor would a caregiver who fabricates medical diagnoses for material gain, or malingering, such as would be the case in a caregiver who fabricates a child’s illness in order to collect a disability benefit on behalf of the child (15). These motivations have been described by Rogers as being either “criminologic” in nature, as in antisocial behavior, or as “adaptational” as would occur in malingering to secure financial gain when faced with a difficult financial predicament (19). Rosenberg highlights the potential variability in motivation of caregivers by wondering if parents who induce illness in their children are ill themselves or if they simply exhibit “nasty, self-serving cruel behavior” (20). Other entities that must be distinguished from factitious disorder imposed on another are those parents of chronically ill children who are perceived as “difficult” or overly demanding by medical staff, and “overanxious” parents who may display exaggerated concern for their children’s health when they feel proper medical attention is not bestowed (18).

Definitional issues also play an important role in the legal aspects of suspected cases of caregiver-fabricated illness. Controversy has played out in courtrooms over whether terms that specify a psychiatric illness in an adult perpetrator may or should be used to prosecute perpetrators of this special form of child abuse. Meadow has suggested that the child victim’s diagnosis of this form of maltreatment be used to identify a “collection of features characterizing a particular form of child abuse” and that diagnosing the adult perpetrators is the task of mental health professionals (13). These tensions carry weight when medical professionals are asked to render diagnoses to be used in court. It is self-evident and prudent that pediatric providers are best able to diagnose child abuse and that mental health professionals are best able to diagnose adult psychopathology.

EPIDEMIOLOGY

The true prevalence of caregiver-fabricated illness is unknown. Active reporting of cases in a prospective study conducted over a 2-year period in the United Kingdom and Republic of Ireland established an annual incidence of 0.5/100,000 children aged under 16 years, and the peak incidence of 2.8/100,000 children in the first year of life (21). A prospective study from Italy that evaluated all patients admitted to a pediatric ward over a period of 28 months found a prevalence of what the investigators termed Munchausen syndrome by proxy in 4 of a sample of 751 patients (0.53%) between the ages of 11 months and 16 years (22).

In 1987, Rosenberg conducted a review of the existing literature and summarized all the published reports (23). These included 117 children in 97 families. Of these cases, the perpetrator was the mother in every case reviewed (98% birth mother and 2% adoptive mother). In 2003, Sheridan conducted a similar review and found 451 cases in which 76.5% of the perpetrators were mothers (20). In Ferrara's study from Italy, of the four cases in which Munchausen syndrome by proxy was diagnosed, mothers were the perpetrators in three, and a grandmother in one of the cases (22). Fathers have previously been found to be only rarely implicated as being the perpetrators or appearing to be complicit in the fabrication of illness, although Meadow published a series of 15 such cases occurring over a 10-year period, and in Sheridan's review, fathers were the perpetrators in 6.7% of the cases (24–27). In a review of cases published outside the United States, Canada, United Kingdom, Australia, and New Zealand, Feldman and Brown reported on 93 cases, and in these the mother was the sole perpetrator in 86% and the father was the sole perpetrator in 4% (24,28). Libow describes the phenomenon of "blended cases" in which a caregiver and a child collude to put forth a false medical presentation (29).

The diagnosis of caregiver-fabricated illness has been made in children of all ages from the first month of life to 21 years, with the mean age being reported as 40 months and 49 months in the Rosenberg and Sheridan reviews, respectively (23,24,28). In the prospective British epidemiologic study, however, the median age of diagnosis was 20 months (21). The mean time interval between the onset of symptoms and time of diagnosis was found by Rosenberg to be 15 months, by Sheridan to be 22 months, and by Ferrara to be 10.3 months (22–24). There are reports of instances in which the condition started prior to birth with mothers inducing preterm delivery (30,31). Male and female children are victimized at equal rates (23,24). A fatality rate of 6% to 10% has been identified in two separate studies (21,29).

CLINICAL DESCRIPTION

Medical Presentation

The variety of medical symptoms in children who present with Munchausen

syndrome by proxy is extensive and includes practically all organ systems. Generally, the illness appears to be multisystem, and the children may appear to have different types of illness at different times. The four presentations that were among the most common in both Rosenberg's and Sheridan's reviews were seizures, apnea, diarrhea, and fevers. Altogether, Rosenberg listed 68 different presentations or pathologic findings, and Sheridan listed 101, highlighting the striking diversity of possible potential presentations of Munchausen syndrome by proxy cases. The means by which the perpetrators caused the symptoms or abnormal findings are just as diverse and illustrate the severity and horrifying nature of the syndrome: One mother had put bleach in her child's eye, causing the appearance of a periorbital infection; others had repeatedly suffocated their children so as to simulate recurrent apnea or seizures. Other caregivers caused sepsis by putting fecal material into their children's intravenous lines (23,24).

In approximately 40% of cases in Sheridan's review, the perpetrator had simulated an illness but had not actually done anything directly to the child to cause harm (24). These were instances where the perpetrator had done something such as putting drops of her own blood in her child's urine or contaminating the specimen. In these instances, although the perpetrator does not herself physically harm the child, her behavior instigates potentially painful investigations and procedures.

Bools et al. have pointed out that there is a significant amount of comorbidity among cases of caregiver-fabricated illness. In a review of 56 cases, 29% had a history of failure to thrive and 25% had a history of either nonaccidental injury or neglect (32). Siblings also might have a history of such findings or might themselves have been the subjects of fabricated illnesses. This appears to be particularly true among cases that have presented as apnea and which, in fact, are owing to suffocation (32–35). Of note, in Sheridan's sample, apnea was the most common presenting symptom, representing 26.8% of all cases reviewed (24). When children present with apnea, caregiver-fabricated illness should always be considered if there is a history of death of a sibling or if episodes of apnea have occurred only in the presence of one person.

Ayoub et al. reported on a series of five families in which educational disabilities were the presenting symptom in cases ultimately diagnosed as caregiver-fabricated illness. This diagnostic entity has been called educational condition or disability falsification. These cases, unlike those which present with medical problems, are played out within schools, among teachers, guidance counselors and principals, and especially within the special education system (36). Another recently recognized subcategory of caregiver-fabricated illness is that in which a psychiatric or behavioral problem is the presenting complaint. This case has involved repeated outpatient visits and hospitalizations for psychotic disorders, multiple personality disorders, attention-deficit disorders, temporal lobe epilepsy with rage, Tourette disorder, and autistic spectrum disorders (37).

Description of Parents

Mothers are most often associated with perpetration of fabricated illness in children, and often have had prior extensive exposure to the health care system. This, in some instances, has been from past training and work experience as a nurse, medical receptionist, or other health care professional. In Meadow's description of 17 families, nine of the mothers had such a background, and Rosenberg reported that 27% of 97 mothers had a nursing background and another 3% had worked in medical offices (23,38). In other cases, the mother herself has a fabrication disorder and therefore has brought to her experience as a mother, both her own psychopathology and often a vast knowledge of medicine, hospitals, and medical practice acquired from her experiences prior to her child's birth. In a study of covert deaths in infancy, one-half of the perpetrators had some form of abnormal illness behavior such as somatization disorder, and 22% were reported to have Munchausen syndrome, or factitious disorder, and in Sheridan's review, 29% of the perpetrators had some features suggestive of factitious disorder (24,39).

Perpetrating caregivers may be considered exemplary in all their interactions with medical staff, or may be adversarial, especially when challenged about the veracity of reported child symptoms. In spite of having outwardly positive relationships with perpetrators, hospital staff have reported subjective feelings of uneasiness or feeling intrusive in the caregiver's presence (40). Some perpetrators are thought to be motivated by a desire to manipulate or control doctors or other professionals perceived to be powerful. In this case it is the deception of medical staff, rather than a desire to somehow join their ranks or be perceived as an ideal mother, that appears to motivate the perpetrator (14). Recently, attention-seeking behaviors have found a new outlet in online blogs on which caregivers share details of their experiences parenting an "ill" child and where commenters can provide gratifying and immediate messages of support (41). Perpetrating caregivers may be considered model parents who are extremely attentive to their children. They may take over the care of their children to a greater degree than is usual in hospitals and often live in the hospital and remain with the child constantly. It has been noted, however, that the care given to the child can be of an excessive nature; for example, the child may be dressed in inappropriately lavish clothing, or the hospital room may be stocked with an outrageous number of toys (40). Prolonged covert videotaped observation of caregivers, however, has often revealed detached or even directly cruel behavior to children when they are not in the public view (12). One striking quality of a perpetrating caregiver that may be important in recognizing the syndrome is her inappropriate affect when given information about the severity of her child's illness or discussing invasive medical investigations. There is a bland acceptance, rather than obvious distress, and she may appear to be relatively at ease with medical uncertainties (40). In one report, the mother was even described as appearing

euphoric as her child became sicker (42).

Besides fabrication of symptoms of illness, these mothers often fabricate extensively about other parts of their lives. An example of this is a mother who made statements that she had just completed a law degree and was working toward a master's degree in Russian history, both of which were false (43). Certainly, an important element of the syndrome is the mother's ability to converse with the medical staff about her child's illness in a very knowledgeable and medically sophisticated manner.

In contrast to the mother's constant presence, a father may have very little involvement in his child's care and sometimes does not even visit the hospital. This is particularly noteworthy considering the severity of the child's illness. In a review of 37 families, 70% of the fathers were described as peripheral or absent from the family system; often the fathers have jobs that keep them away from the family for prolonged periods of time (38,44). The marital relationship between the parents is often poor, although in some instances the child's apparent illness serves to bring the parents closer together.

In rare instances where fathers have been identified as the perpetrators of illness fabrication in a child, their interactions with medical personnel appear quite different than is the case with mothers. Like mothers, the fathers often stay with their children in hospital, but are considered by staff to be demanding, overbearing, and unreasonable, and are often quick to make formal complaints and seek legal redress. It is notable that in Meadow's description of 15 fathers, none were actively employed and 11 had factitious disorders (27).

Description of the Child

There is little in the literature describing the children in this disorder. Older children in particular may collude with their mothers in the ongoing deception. In the original report of Sneed and Bell, it was the 10-year-old boy who was presenting the pebbles as renal calculi (3). Furthermore, these children, like children who have been repeatedly physically abused, may learn to tolerate passively medical procedures. A harrowing look into the experience of a child abused by a mother, a registered nurse, who fabricated illness at one point by tying him/her to a chair and repeatedly beating his/her foot with a hammer can be found in a published account of an adult survivor of the disorder (45). A separate diagnostic entity has emerged from these observations, that of child and adolescent illness falsification. Children who induce or fabricate illness are thought to do so either as a continuation of perpetration of factitious disorder by a parent or covert parent coaching, or because of a strong attraction to the medical world in themselves (46). Other symptoms that have been described include feeding disorders among infants and toddlers and withdrawn, hyperactive, or oppositional behavior among preschoolers (41).

ETIOLOGY

Understanding of the perpetrators of fabricated illness in a child is evolving. Overall, perpetrating caregivers are likely to need or benefit from having a well child being perceived as ill, or a sick child being perceived as more ill than the child actually is (11). Two systematic reviews of perpetrators identified high rates of somatoform disorders, coexisting personality disorders, and a history of self-harm in mothers who fabricated illness in their children (47,48). Adversity in the perpetrator's own childhood also is an important etiologic factor. Family disruption and loss were prominent in Bass and Jones' sample (48). Others have found high rates of physical and sexual abuse in perpetrators (24,44,47). These studies shed light on perpetrator behavior that may be understood as a maladaptive coping strategy in the face of psychic distress, and reveal reasons why children are used as tools for interaction with the medical system (12). An abnormal attachment between the mother and child is postulated to underscore the motivation of perpetrators in caregiver-fabricated illness, possibly in concert with childhood adversity and a personal history of somatization behavior (11). Review of surveillance videos reveals that mothers thought by medical staff to be extremely caring largely ignored their children when alone with them (49,50). In a report by Nicol and Eccles, the mother reported that "she found, in her general practitioner, a source of support and kindness and this reinforced the pattern of very regular attendance at the surgery" (51). Guandolo has commented that "illness is the ticket of admission to a place where understanding and caring relieved the feelings of hopelessness and isolation" (43). Perpetrators also may find a sense of self-worth and importance through interactions with the medical world. Chan and associates described a mother who would visit the intensive care unit just to talk to other mothers, and Meadow has described another mother who had some nursing training and who would help teach nursing students (26,52). In the case discussed by Nicol and Eccles, the mother reported that she liked to feel that she "was being considered by intelligent people" (51). Pathologic lying may be an important comorbidity for perpetrators of fabricated illness. Waller has commented that "the disturbance in thought content and behavior may be a dissociative phenomenon or a form of pseudologia phantastica or pathologic lying in which the parent comes to believe, at least intermittently, the fantasy that the child has a primary rather than a factitious illness" (53). Bass and Jones highlight the importance of pathologic lying in their sample as well, noting that the behavior emerged in the setting of life stress and encompassed other domains of deceit including making hoax telephone calls to the police about invented "harassment" (48).

SPECTRUM OF THE DISORDER

Meadow, in reporting on what he terms mild cases, raises questions regarding the

limits of the definition of the disorder. He points out that, at times, caregivers often exaggerate their children's symptoms or may perceive that a problem is present when it is not apparent to the doctor (54). Perpetrators may themselves move along a spectrum by initially exaggerating a real symptom, to fabricating symptoms, to physically inducing symptoms in their child (17). Bass and Glaser frame the spectrum to begin with "erroneous reporting" of medical history, symptoms or signs and progress to "deception by use of hands" which includes falsification of medical records, tampering with specimens of intravenous lines, or induction of illness by, for example, poisoning or suffocation (11).

DIAGNOSIS

The challenge inherent in making a diagnosis of caregiver-fabricated illness cannot be overstated. Pediatric providers are taught to ignore parental concern at their peril; the shift from a partnership with a parent in the care of a child to a relationship in which the parent is suspected of lying about or actively harming a child is a dramatic one. Furthermore, medical providers may become unwitting agents of abuse as they order diagnostic tests and treatments for children based on parental misrepresentations or deceit and this may render these providers even less likely to recognize the pathologic behavior of perpetrating caregivers. The American Academy of Pediatrics suggests that the following three questions be posed when caregiver-fabricated illness is suspected:

1. Are the history, signs, and symptoms of disease credible?
2. Is the child receiving unnecessary and harmful or potentially harmful medical care?
3. If so, who is instigating the evaluations and treatment? (17,55).

A full review of medical records, which can be voluminous, is indicated. Consultation with a child abuse pediatrician may provide needed expertise and objectivity that treating providers will necessarily lack (17). The American Academy of Pediatrics suggests the following as indicators of possible caregiver-fabricated illness:

- Diagnosis does not match the objective findings
- Signs or symptoms are bizarre
- Caregiver or suspected offender does not express relief or pleasure when told that child is improving or that child does not have a particular illness
- Inconsistent histories of symptoms from different observers
- Caregiver insists on invasive or painful procedures and hospitalizations
- Caregiver's behavior does not match expressed distress or report of symptoms (e.g., unusually calm)
- Signs and symptoms begin only in the presence of one caregiver

- Sibling has or had an unusual or unexplained illness or death
- Sensitivity to multiple environmental substances or medicines
- Failure of the child's illness to respond to its normal treatments or unusual intolerance to those treatments
- Caregiver publicly solicits sympathy or donations or benefits because of the child's rare illness
- Extensive unusual illness history in the caregiver or caregiver's family; caregiver's history of somatization disorders (17).

Greiner et al. have piloted a screening tool for early identification of what they term medical child abuse. The authors employ a 15-item checklist for medical record review that had a sensitivity of 0.947 and a specificity of 0.956 ($P < 0.05$) in detecting medical child abuse (56). While covert video surveillance has been proposed as a tool in the diagnosis of caregiver-fabricated illness, it is highly controversial and fraught with ethical concern. A key issue is the need for continuous monitoring of such surveillance in order to allow for immediate intervention in the case of witnessed child harm (57–59). A retrospective review of 41 cases in which covert video surveillance was used to investigate a possible diagnosis of Munchausen syndrome by proxy in one pediatric hospital found that 23 diagnoses were actually confirmed. Of these 23, covert video surveillance was seen as crucial to making the diagnosis in 13 cases (56%) and supportive of the diagnosis in 5 cases (28%) (58). Careful and complete record review (which may be arduous and require collecting data from multiple sources) and in person meetings of all currently involved medical providers are likely the most useful means of detecting caregiver-fabricated illness. Once identified, caregiver-fabricated illness must be promptly reported to child protectiveservices.

TREATMENT

Treating perpetrators of caregiver-fabricated illness is difficult. While some perpetrators admit deceit when confronted, many actively deny it. Schreier has identified the following conditions under which treatment may be successful: (1) the abuser admits to the abuse and has been able to describe specifically how he or she abused the child, (2) the abuser has experienced an appropriate emotional response to his or her behaviors and the harm he or she has caused the child, (3) the abuser has developed strategies to better identify and manage his or her needs to avoid abusing the child in the future, and (4) the abuser has demonstrated these skills, with monitoring, over a significant period of time (60). Challenges inherent in meeting these conditions including the likelihood that the suspected perpetrator has experienced severe adversity in childhood, makes the establishment of both a therapeutic relationship hard and the capacity for self-reflection potentially limited (11). Some mothers have become extremely agitated, acutely psychotic, or depressed

and suicidal following the confrontation (61). An assessment may be required regarding the need for psychiatric hospitalization. Child victims of caregiver-fabricated illness may require a variety of treatment strategies including physical rehabilitation, trauma-focused care, and grief support in the wake of being separated from an abusive caregiver. Family-centered care may be crucial for both rehabilitation of offending caregivers and support of nonoffending family members (16).

OUTCOME

The final outcome for child victims of caregiver-fabricated illness is variable and dependent both on the severity of the disorder and treatment provided. The caregiver who has additional psychiatric disorders and who has been involved in the fabrication of symptoms or has suffered from pathologic lying for many years is more difficult to treat than another with a simpler presentation. This is likely true for those caregivers who have factitious disorder themselves, which is often very difficult to treat successfully (62). The child whose symptoms of illness has been caused by a more dangerous activity (e.g., suffocation) is obviously at higher risk of dying than the child whose symptom was owing to less dangerous methods (e.g., a mother's putting blood in her child's urine). In Rosenberg's review of the 117 cases reported in the literature, 9% died and 8% of the survivors had permanent disfigurement or impairment of physical function. The leading causes of death were suffocation and poisoning (23). Children have died even after the diagnosis was made and their mothers confronted, and younger siblings have been abused after older siblings have died. The psychiatric sequelae of caregiver-fabricated illness have been less well described, both for the mother and child. Certainly, some of these children have continued to fabricate illness for themselves, and child victims of fabricated illness may grow up to fabricate illness themselves (54,63). Of the 12 children described by McGuire and Feldman, 11 were described as having adverse effects that included immaturity, abnormal relationships with their mothers, separation problems, and aggressive behavior (41). Some children have expressed fears of poisoning and death, and at least two children have required psychiatric hospitalization (6). Bools et al. described 54 children for whom they obtained information an average of 5.6 years after the event. Thirty of these children continued to live with their biologic mothers, whereas 24 children were with other family members or in substitute care. For 10 of the 30 children living with their mothers there was evidence of further fabrications, and for another 8 there were "other concerns," either about the relationship between the mothers and their children, or about other aspects of the mothers' behaviors. Of these 18 children for whom there were continuing concerns about the family, 12 exhibited psychological symptoms, including somatic complaints, emotional disorders, conduct disorder, and poor functioning at school.

Among the 24 children who were no longer living with their biologic mothers, 8 had persistent psychological symptoms, and another 6 children had disorders that had shown signs of gradual improvement. Altogether, the authors of the study concluded that half of the children had outcomes that they considered to be unacceptable, but because of the variability in cases, it was not possible to comment on whether better outcomes were obtained when children remained with their mothers or were separated. However, the authors did conclude that when children remained with their mothers, the outcome appeared improved when there had been a temporary placement in foster care (63). Some children are "quite indifferent" to separation when it does occur, and that they go on to embrace their own wellness and engage with others around them (64). In reporting on the follow-up of cases enrolled in an intensive, inpatient treatment program, Berg and Jones reported greater success. When 16 families were reevaluated at an average of 27 months after treatment, there were no ongoing concerns for nine of the families; the mothers had no mental health problems and had insight into their original condition, and the children had no psychological disorders. There continued to be mild concerns for five families in which the mothers continued to have mild to moderate mental health problems, although these did not impact on their relationship with their children or on the children's development. In only two families were there more serious concerns about the mother's mental health, although they were not overtly abusive. However, the authors stressed that these cases had been selected for treatment on their likelihood of achieving success and that cases considered unsuitable for psychiatric treatment were excluded, usually because of persistent parental denial or the severity of the parent's personality disorder (65).

CONCLUSION

Timely recognition of caregiver-fabricated illness can prevent harm in children. In this condition, perhaps more so than in any other, there needs to be extensive collaboration among all involved medical disciplines. Early involvement of an expert in child abuse pediatrics may be crucial both to the objective evaluation of a case as well to needed coordination among all involved medical providers.

CHAPTER 5.15.5 ■ CHILDREN EXPOSED TO MASS EMERGENCY AND DISASTER: THE ROLE OF THE MENTAL HEALTH PROFESSIONALS

NATHANIEL LAOR AND LEO WOLMER

INTRODUCTION

Mass disasters, whether natural, technologic or human made, affect individuals, families, and entire communities and impose incalculable physical, psychological, and economic hardships on survivors. In recent years, apparently as a result of increased population density, urbanization, and climatic changes (1), we have been witness to significant growth in the mortality associated with nearly all types of disasters. From 1980 to 2000, about 75% of the world's population lived in areas that were affected at least once by some form of disaster, whether an earthquake, a tropical cyclone, flooding, or drought (2). Each year from 2000 to 2009, 110,000 lives were lost and 255 million people were affected by disasters (3).

In this chapter, we focus on the psychosocial impact of disasters on children. Physical damage is usually easy to identify, but the internal suffering of children can remain hidden even from the most sensitive observers. Therefore, clinicians and researchers have invested efforts in explaining the type, extent, and risks of children's maladaptive responses to mass disaster.

Garmezy and Rutter (4) claimed that children show only a mild response to traumatic conditions. Modern empirical methodologies and clinical observations have refuted this claim, revealing that the adverse psychological effects of such conditions can be severe and long lasting (5–9) and may persist even in the face of apparently normal social functioning (10). Yet according to the Task Force Report of the American Psychological Association, "few psychologists have had specific training for working with children after disasters, and discussions of children's responses to disasters have been rare in texts on psychopathology or issues in normal development" (8).

This chapter has the following objectives: (a) To offer a theoretical perspective of disaster as a systemic social phenomenon; (b) to clarify the role of child mental health professionals in large-scale preparedness and community reactivation under conditions of disaster; (c) to review the major findings on children's responses to disaster; and (d) to propose assessment and intervention models for children, families, and communities exposed to mass disaster.

DEFINITIONS

The literature distinguishes between "traumas" and "disasters." *Traumas* are experiences that threaten the individual's health and well-being, render the individual helpless in the face of intolerable internal or external danger, overwhelm coping mechanisms, violate basic assumptions about survival, and accentuate uncontrollability and unpredictability of the world (11). Traumas may be caused by an isolated, unanticipated, and uncontrolled event or they may be long lasting, the result of repeated exposure to several extreme external events (12).

Disasters are relatively abrupt events that are somewhat delimited by time. They are public events that cause extensive damage to property and lives and that have a total and ongoing disruptive impact on children and families' social networks, basic daily routines, and sense of safety and connectedness (8,13,14). During a disaster, the community's capacity to negotiate the recovery of its individual members is compromised. Matters are often made worse when resources are overextended (1) and the community's infrastructure is affected, often resulting in unemployment, housing and food shortages, poor health, deficient school and mental health services, job absenteeism, and family dysfunction.

Unlike traumas, in disasters victims must face immediate, long-lasting, and repeated exposure to reminders of the event. Disasters usually involve three interconnected types of experiences: terror due to objective and subjective threats to life or exposure to horrifying sights; grief following loss (e.g., human lives, sense of meaning, basic trust, self-esteem); and disruption of normal life (15). On the social level, disasters are accompanied by shock, depression and mourning, confusion and social disarray, rage and blame, the collapse of formal leadership, and social disintegration. Children sense that their family, neighborhood, and school have been disrupted (13). The recovery processes continues long after the disastrous event itself is over. Hence, theoretical, research, and intervention studies should be both all-encompassing and oriented to the long term.

DISASTERS AND THE MENTAL HEALTH SYSTEM

Mass disasters pose a multifaceted challenge to the mental health system (16): (a) *Environmental challenge:* Substantial needs, routinely defined as pathologic, emerge and must be confronted; (b) *Systemic challenge:* Multidisciplinary orientation and multisystemic collaboration are required to counter the impact; (c) *Practical challenge:* Problems to be faced involve resource allocation, extended deployment, organization, dissemination of information, and communications; (d) *Theoretical challenge:* The mental health system lacks a comprehensive and integrative "mass disaster theory" with a general social perspective in addition to the public health perspective (17); and (e) *Professional challenge:* Most programs are not committed to disaster intervention training. Hence, professionals have insufficient knowledge and little resilience in the face of ongoing stress.

DISASTER STAGES

The various models proposed to describe the response to disaster focus mostly on the event perspective (e.g., warning, threat, impact, inventory, rescue, and recovery) (18). The systemic–ecologic model proposes a conceptual framework of disaster that integrates the event, the individual, and the sociocultural reaction, including the mental health response (19). Such a perspective has been called for in the field (20,21). According to such a perspective, a disaster comprises a series of four stages that can start long before the expected event actually takes place (e.g., the months of anticipation preceding the outbreak of a war). This first *pre-disaster stage* includes warning, alert and alarm signs, and a sense of massive threat to communal and personal security. This is the stage in which efforts should be made to build preparedness and resilience.

The *second stage* includes the damaging event itself, the primary disaster, and the attempts to alleviate its effects, i.e., rescuing as many victims as possible and providing basic needs (food, water, and shelter) to the affected population. The *third stage* involves massive changes in societal structure and function (establishment of evacuation centers and tent-cities, movement of refugees), which may lead to a breakdown of societal norms, structures, and functions. This breakdown, reflected in societal regression, may be viewed as the secondary disaster. Life usually stabilizes in due course, generally after 18 to 36 months. At this point, a *fourth stage* of disaster may ensue, wherein the sociocultural losses of the tertiary disaster may threaten the existing cultural matrix and identity, which may be followed by the emergence of extremist ideologies (22,23).

When the severity of the damage evolves gradually and over an extended period of time (e.g., AIDS epidemic in Africa), primary, secondary, and tertiary types of disaster coexist. This gradual pattern allows for preparation and short-term adaptation to minor increments of destruction. Yet it may also prompt habituation (24) within both the affected and the international communities, hence damaging the capacity for long-term forecasting and proper coping.

HOW CHILDREN REACT TO DISASTER: THE DISASTER SYNDROME

A child's protective matrix consists of various dimensions in his or her reality and inner experiences that can be disrupted and rehabilitated, among them political, cultural, social, physical, familial, maternal, and personal dimensions (25). Since disasters affect all these components, unlike posttraumatic syndrome, the disaster syndrome involves all aspects of a child's developing cognitive structures and capacities and poses a more intricate pathologic threat. Children must cope with many different kinds of losses: of people, of support systems, of normal routines, of

attachment figures, and of basic assumptions of safety and normalcy. Children may become withdrawn and alienated from the reality they perceive as having betrayed them: nature, parents, society, and technology (20,26,27).

According to Franks (28), disasters impact "moving targets." In other words, children continuously change and mature when disasters strike. Thus, disasters change the context in which child development occurs, and hence change the course of development itself. Franks emphasized the need to approach affected children not only by examining symptom levels but also by focusing on qualitative cognitive and emotional development and age-appropriate functioning.

Disasters may affect children's ability to regulate the intensity of their impulses and unconscious fantasies, consequently jeopardizing their sense of self-efficacy, security and autonomy, the normal maturation of their defensive functioning, object relations, reality testing, and attachment. Structural developments, such as superego consolidation and its behavioral consequences, ideal ego structure formation with its relevance to affiliation and ideology development, and ego functions with their significance in areas of cognition and attention, may also be hampered. Traumatization has a potentially damaging effect on the development of a lasting sense of identity and of the historical continuity of the self that integrates thoughts, images, feelings, and sensations (29).

Preschoolers may exhibit behavioral changes and regressive behaviors, mostly within the normal range. These may include irritability, sleep difficulties, separation problems, fears, nervousness, posttraumatic play, demanding or dependent behavior, whining or temper tantrums (30–34). Furthermore, parents and close individuals seem to play a significant role in preschoolers' responses. As Wolmer et al. (35) found among Israeli preschoolers who endured lasting massive rocket and mortar attacks, those who were more exposed to harsh description of the traumatic event and to severe emotional responses in their close surroundings suffered from more PTSD and impairments in functioning. However, the issue of who impacts whose response in the parent–child dyad remains unclear, as studies show, for example, that more, and not less, maternal emotional sensitivity appears to mediate the development of the child's PTSD (36).

Older children may report disturbances in conscience functioning, although their moral functioning may seem advanced (37), as well as risk-taking behaviors such as substance abuse (34).

Studies suggest that parents and teachers tend to report fewer posttraumatic symptoms (PTS) in children than the children themselves report (21,38–40). Adults may be preoccupied with their own stress and not be attuned to their child's inner emotional states. Children may also be more reliable reporters of internalizing or dissociative symptoms. Thus, clinicians must be careful to assess children's functioning directly and not rely exclusively on external reports (21). They must bear in mind that while the initial response tends to predict later adjustment, initial

symptomatic ratings may not correlate with later assessments (41), and posttraumatic responses may have a delayed onset (42), although this does not occur frequently (43). If a disaster is limited and well controlled, most of the pathologic reactions in children will abate within the first year (21,41). If community functioning is substantially disrupted, however, symptoms may persist for years (5,10,21,42).

RESPONSE TRAJECTORIES

For quite a while, research has focused on broad comparisons (i.e., exposed and unexposed populations) or on extreme dysfunction. In the last several years, however, growing interest has focused more closely on the individual (21). For the most part, individuals seem to have intense reactions to an event. Yet, unless the individual is repeatedly challenged, these reactions will likely subside within a month (34). Others may nonetheless experience symptoms later on, peaking approximately within a year, yet recover (44). Among those who continue to experience significant distress, many continue to suffer a great deal longer (43).

On that note, it is important to distinguish resiliency from lack of reaction, or resistance. The term resiliency does not refer to a total absence of psychological distress in the face of adversity but to the ability to remain functional in the face of adversity or to recover and adapt quickly. Resilient individuals consistently present responses, even intense ones, in the short-term postdisaster time frame, yet are able to reassume functioning after a short period of recovery (45).

Different trajectories of responses to disasters seem to exist: resilience (the most common, a mild disruption in functioning followed by a return to baseline within a few weeks or months); recovery (characterized by a more intense response associated with moderate-to-severe levels of distress and disruption of functioning that subsides approximately 1 to 2 years postdisaster); delayed response or “late onset” (a rather mild–moderate levels of distress followed by a rise in dysfunctionality); chronicity (the least optimistic response characterized by an immediate and severe reaction that could last for years if not permanently); and posttraumatic growth (following struggles with acute crises), some people report more meaningful relationships, increased personal strength and appreciation for life, and richer spiritual lives (21,22,46). Some of these trajectories may not be mutually exclusive (e.g., PTS and posttraumatic growth).

POSTDISASTER SYMPTOMS

In response to disasters, children may exhibit a combination of some or many of the following behaviors: posttraumatic stress symptoms, fears, anxiety, behavioral problems, physical symptoms, depression and grief, dissociation, and substance

abuse (21,33,47,48). Anthony et al. (49) found that anhedonia, inattention, and learning problems are the most common symptoms after disasters. But rather than being markers of a pathologic reaction, such symptoms reflect the normal disruptive consequences of disasters.

Symptoms of posttraumatic stress disorder (PTSD) are grouped under three domains: intrusion, avoidance/numbing, and arousal. Empirical studies have identified certain symptoms that are specific to children, such as persistent posttraumatic play, omens, separation anxiety, fear of strangers, monsters or animals, and somatic complaints (50,51). Scheeringa et al. (52,53) proposed the following diagnostic criteria for young children. These were integrated into DSM-5 and identify preschoolers' PTSD by a lower threshold for the avoidance and the hyperarousal domains, thereby increasing the prevalence of diagnosed preschoolers following disaster.

Intrusive re-experiencing of the event may be observed in thoughts, feelings, or sensations. Children may retell their experiences over and over, report nightmares, and exhibit repetitive trauma-related play. They may also describe *vivid* traumatic images: visual (mutilated bodies), auditory (sound of the earthquake or screams for help), olfactory (odors of burned bodies), or kinesthetic (feeling as if they were buried under the rubble).

Avoidance of reminders is manifested in the evasion of places, people, thoughts, or activities associated with the disaster. Such avoidance can be both a symptom and a defensive maneuver to reduce internal stress. Nevertheless, persistent avoidance coping is associated with negative mental health outcomes (54). The avoidance may be active (purposeful engagement in thoughts unrelated to the trauma) or passive (not engaging in social interactions) (49).

General psychic numbing may be considered a mild dissociative response and is more difficult to detect in children than in adults (39). Children exposed to disasters may lose interest in activities that were significant in the past, feel estranged from others, exhibit constricted affect, lose recently acquired developmental skills, and express a sense of foreshortened future.

Increased arousal symptoms include irritability, angry outbursts, exaggerated startle response, hypervigilance, difficulty in concentrating, and sleep disturbances such as difficulties in falling asleep or in sleeping alone (55). Although disasters can induce a variety of symptoms, PTS seem to best predict overall distress (56). PTSD following disaster was also found to be directly linked to exposure to the events and to mediate the indirect association between exposure, test anxiety, and depression symptoms (57).

Mass disasters typically induce specific *fears and dependent behavior* in children (32,58). Old fears may be reactivated, current ones may increase, and new fears with a more or less clear relationship to the event may emerge. Fears may lead to dependent and clingy behavior, difficulty separating from caretakers, or refusal to

attend school, thereby damaging overall and specifically academic functioning as well as interrupting the separation–individuation process. According to Vogel and Vernberg (8), disasters challenge children's basic assumption that the world is a secure place, leaving them helplessly vulnerable. Empirical support for this hypothesis was provided by the finding that 5 years after a disaster, young children's symptoms still correlated with their mothers' reactions (59).

Children exposed to disasters may exhibit symptoms of *depression and grief,* but these are usually of lesser severity than are PTSD symptoms (8). Since grief and posttraumatic stress symptoms may appear independently, separate diagnostic interviews are required for each domain (21,60). Grief symptoms can further escalate into traumatic/complicated grief, mostly after firsthand exposure to horrifying sights, particularly loss of loved ones (21). The mood symptoms, which have been suggested to be at least partially secondary to the posttraumatic reactions (61) and now are thought to be independent of them (21,48), are the result of different types of loss (home, family members, personal belongings, basic assumptions). The traumatic grief reaction, previously defined for adults (62), is today also defined for children (63).

After the 1999 earthquakes in Turkey, Laor et al. (64) found that children who had seen severely injured or dead people, experienced hunger or lack of sleep after the event, or had undergone more traumatic experiences in the past, reported more depressive/grief symptoms. Furthermore, following hurricane Ike, La Greca et al. (65) showed that more immediate (e.g., relocation) and ongoing (e.g., still living in a house with a leaking roof) hurricane-related loss and disruption significantly predicted depressive symptoms.

Disasters may also be perceived as an overwhelming interruption of human experience, thereby distorting an individual's basic assumptions, both cognitive ("What is real and what is imaginary?") and existential ("Is it happening to me?"). To re-establish well-being, some people define a different "spatial" arrangement of their position relative to the world: "I am not affected because I am elsewhere." This type of distancing is adaptive. Pathologic *dissociation* goes one step further, with manipulation of adverse stimuli through the reconstruction of perception and the splitting up of consciousness: "What is happening to me is not real" or "I, who am experiencing this, am not real" (25).

Dissociative reactions may be manifested by symptoms that reflect a discontinuation of personal experience. Children may have out-of-body experiences, perceive life as a dream or a movie, and "see" or "hear voices" of people who died. Amnesia is apparently less frequent in children than in adolescents. Dissociative mechanisms may provide temporary relief from the overwhelming trauma. If they persist, however, they may engender a long-term alteration in normally integrative functions of identity, memory, and/or consciousness (66).

FACTORS AFFECTING CHILDREN'S RESPONSES TO DISASTERS

Several categories of factors have an impact on the scope of children's symptomatic responses to disaster.

Disaster-Related Factors

Children whose traumatic exposure is more severe tend to react in a more extreme manner (20,21,34,48,57,65,67,68), and these effects can even be transmitted to the next generations (20). This "dose-exposure" effect is apparent, for example, in the child's proximity to the epicenter of an earthquake (69), the impact zone of a hurricane (70), or the site of missile attacks (31). In a 5-year follow-up study after a technologic disaster in the Netherlands, Boer et al. (33) found that compared to children who had not been exposed, exposed children suffered from more physical, behavioral, and emotional symptoms.

More severe responses have been noted in children who were exposed to extremely harsh experiences, such as witnessing severely injured people and mutilated bodies and being faced with a direct threat to their own lives or those of their parents. Subjective perception of threat seems to have a larger impact than objective threat (21,43). Severity of response is also associated with suffering human loss, especially of family members (71,72), as well as sustaining personal injuries (61,73,74). Continuous displacement also predicts the degree of psychological response (10,43,75), and children exposed to several traumatic experiences are more likely to exhibit a greater number of PTS (76,77).

In cases of severe disasters, children need to cope with a massive range of problems: lack of food, water, and shelter; property damage; inadequate housing; violence; lack of medical care; traumatic reminders; bereavement; relocation; separation from parents; impact on caregivers' functioning; and economic crisis. Under such circumstances, their posttraumatic reactions may intensify and interfere with symptomatic recovery as well as with their long-term development (21,29,67,69,71,78). According to a meta-analysis across 96 studies linking disaster and PTS among children (79), exposure was associated with greater distress when involving greater loss of life in general, closer proximity to the event, greater perceived threat, and personal loss.

Child-Related Factors

Age

Due to methodologic limitations and variations both in subject age and in symptom

domains as examined by different studies, generalization needs to be considered with caution. Younger children appear more vulnerable (21,24,80) because at the time disasters strike they are still developing (81). Behavioral problems, specific fears, regressive symptoms, sleeping problems, separation problems, and PTSD appear to be more characteristic of young children, whereas depression and anxiety are more characteristic of older children and adolescents (21,33,67,82).

It should be noted, however, that while older children are less vulnerable, they are more exposed to the disasters and their impact on their communities. They are more aware, mobile, and exposed to the media and social networks (68,83).

Gender

Results regarding gender differences are more consistent, though still call for cautious interpretation. Girls appear to be more likely to suffer from greater distress and PTSD than boys (20,21,34,65,79,81). While some studies reported no gender differences (10,31,70), most found that girls tend to report more internalizing symptoms (anxiety, depression, fears) and PTS, while boys exhibit more externalizing behavior (acting out, aggression) (69,74,82,84). Girls are also more prone to utilize maladaptive and emotion-focused coping strategies (20). It has been suggested that girls experience more objective trauma, prior trauma, and postdisaster stressors (85), which consequently lead to their more intense response.

Gender and age differences need to be studied further, especially considering most data are collected via adult reports and often with no comparison groups (20,21,68).

Vulnerabilities and Resiliency

Children with prior pathology, particularly anxiety and learning difficulties (54,74,75), those who have suffered more traumatic events in the past (34,77,86) or must cope with disabilities (87), and children with negative affectivity (57) are more prone to severe symptoms months after a disaster. By contrast, resilient children are those who have the support of caring adults during and after major stressors, as well as those who are good learners, good problem solvers, able to engage with other people, and possess an internal locus of control (88). These children have areas of competence and are perceived to have high efficacy (89,90). Resiliency in children is also associated with secure attachment, better cognitive skills, overall predisaster functioning, self-regulation, faith, and hope (20,34,68). Moreover, Asarnow et al. (54) found that children's reactions to the Northridge earthquake, a mild-to-moderate stressor, showed that the role of heritable biology was minor compared to the role of the children's subjective appraisals of stress and past psychopathology.

Coping Skills

A child's coping skills also mediate between exposure severity and response. More immature coping/defensive strategies for dealing with stress (blaming others, anger) are associated with greater symptomatic persistence over time (55,91). Coping has a bidirectional association with a child's distress. The distress following disasters elicits the use of coping strategies, which later affect the distress, with appraisal processes playing a key role (81).

Biologic Factors

One of the most innovative frontiers in disaster research is the role of psychobiology in disaster response. For example, it was found that possessing a certain gene associated with the Met allele of the brain-derived neurotrophic factor (BDNF) moderates how disaster exposure is linked to PTSD and depression levels, with a stronger association found among those in possession of this gene. This was moderated by children's social support, with a stronger association between exposure and PTSD among those with the allele than among those without it, under conditions of low social support (65). Furthermore, a combination of higher cortisol and sympathetic nervous system activity is associated with potential resilience (92). Variations in the serotonin transporter gene (5-HTT) and variations in genes that regulate the functioning of the hypothalamic–pituitary–adrenal (HPA) axis were also found to be significant in stress response (20).

Socioeconomic Status

Low socioeconomic status (SES) has frequently been found to be a vulnerability factor for severe response to disasters. Lower SES is associated with a higher degree of exposure to the event since lower SES populations tend to inhabit more disaster-prone areas (20). Low SES individuals are also at elevated risk for postdisaster problems (67), possibly due to difficulties in rebuilding their lives, such as resecuring housing, food, finances, and receiving loans. Being a member of a minority group is also associated with poor disaster outcomes (65), probably mostly via lower SES and the challenges related to it (21,93).

Family-Related Factors

Parents' Reactions

The presence of adults caring for a child during and after a major stressor is considered the most important and consistent protective factor (86,89) and the way these adults function can mediate the connection between the disaster and the degree of response to it (34). Indeed, the reaction of parents, especially the mother, to a

disaster is generally correlated with the severity of the child's responses, especially among young children (68,94). Researchers found that the reaction of preschool children to the missile attacks during the Gulf War was highly correlated with the reaction of their mothers (10,31,59). This was true for 3 to 4 year olds, but not for 5 year olds, probably owing to the older children's increasing autonomy and the control of psychological buffering systems for development (89). Five years after the war, poor psychological functioning among mothers was associated with heightened symptoms in their children (95).

Parents' ability to contain the anxiety generated by extreme threats of disasters seems to be the most important factor influencing their children's responses (78,96). Parents are critical mediators of stress, mainly owing to their roles in social referencing (pooling information and processing of meaning), responding emotionally, and caring for the child (89).

Family System Role

The family is an important mediating factor, particularly in young children (10,31,97). Families with extreme levels of cohesion—boundaries that are either too loose or too rigid—may not provide the appropriate support or allow the child to withdraw at times in order to process traumatic experiences and reach a constructive resolution of concerns. Caring support, open communication patterns, and sensitivity to the child's needs enable parents and children to regulate dyadic processes and discuss disaster-related issues when necessary. Stressed parents may be preoccupied with their own suffering and may tend to overprotect the child, thus interfering with the healthy process of resolution (78,98,99). Lower parental support and parental overprotectiveness are both associated with child PTSD (100). Findings suggest that stressful experiences during disaster may affect not only the behavior of individuals and culture but also intergenerational transmission of trauma-related biologic vulnerabilities (101,102).

Societal and Cultural Factors

Friendships

Friendships are valuable sources of reciprocal affection and attachment, mutual assistance, emotional security and self- esteem, and nonfamilial contexts for intimacy, thereby contributing to the child's ability to cope with stress (103). Natural sources of friendships—the family, the neighborhood, and the school—may be shattered in times of disaster (21). Friendships may also include supportive relationships with teachers or other adults (38,74). Even the presence of one concerned and caring adult may do much to offset the impact of misfortune in the lives of children (90). And to the contrary, poor child–teacher relationships have

been found to increase the risk for child psychopathology following disasters (104). In fact, social support constitutes one of the most important protective factors for children during disasters (105), especially perceived support (21).

Community

The impact of disasters on whole communities and the need to focus on their functioning as a unit in order to improve the well-being of their members are matters of growing concern worldwide (20,21,105). Disasters change the layers of support in the community. Individuals tend to rely more on existing elements despite outside assistance, people perish or move away, and those who stay suffer themselves and thus are less available to support others (21). Communities mobilize at times of disaster by relying on their inner strength and external backup support.

Culture

Cultures define the terms under which symptoms are expressed and set the parameters for expression of personal distress. Some cultures encourage children to express their feelings of distress, while others do not. For example, in some cultures adults may admonish children who were victims of disaster to be prim and proper or to refrain from crying (58,106). Thus, cultural background, with its strengths and its weaknesses, needs to be taken into account by clinicians when planning treatment interventions. In addition, culture also mediates ideology and identity. As the purveyor of the meaning ascribed to disastrous events and consequences, culture regulates the individual's capacity to maintain an active and resilient stance. Yet a traumatically grieving culture may succumb to expressions of mourning and aggression, and when faced with further threats could fuel a cycle of violence. Child soldiers in Africa (107) and adolescents living with ongoing terrorism, war, and intractable political conflict (108,109) are examples of the establishment of a cycle of violence.

Media

The media can play a vital role both during and after disasters, mediating the level of symptoms experienced subsequently (34). News coverage tends to include intensely graphic visual material (21). The extent to which the media can impact the degree of exposure naturally varies depending on media availability (20). In general, exposure through media can be extensive during and after such events (110) and is associated with greater psychopathology and distress, mostly PTSD (111–114). Younger children can be more affected by the media because they do not fully comprehend what they see, are more sensitive to parental reactions, and may not understand that they are watching the same event over and over (28). The general recommendation is

to closely monitor children's exposure to the media, especially that of young and sensitive children (20).

CHILD ASSESSMENT UNDER DISASTER CONDITIONS

Children at risk of psychopathology after exposure to disaster should be identified and treated as early as possible. Efforts must also be directed toward reactivating society's childcare systems via existing childcare workers. In a natural setting, assessment (i.e., screening) may be integrated into normal institutional activity (see the section on The School Setting below). Moreover, pediatricians and primary care physicians, who are usually not trained in trauma assessment and care, should be educated and integrated in the process, because on many occasions survivors turn to them first for assessment and treatment (34). For example, through a relatively brief training intervention following 9/11, physicians educated about mental health issues and screening tools were able to assimilate such practices as part of their assessment and test for psychological problems. These physicians subsequently referred fewer patients to mental health professionals (115).

The preferred clinical screening tools are those that directly assess the child rather than relying on external reporters. Such tools should also be simple and quick to administer, accurate, replicable, sensitive, and specific (116,117). The criteria for identifying pathologic cases should be tempered by consideration of the psychological and economic costs of possible false positives and false negatives. The use of cutoff scores may facilitate the decision-making process, but can obscure minor but "real" differences between children with scores slightly above or slightly below threshold. Green (118) suggested that clinicians think in terms of degree of impairment in a given sample rather than in terms of case identification. Moreover, the assessment of a single domain rather than a complex of posttraumatic, dissociative, and grief symptoms may decrease the sensitivity of the battery (116). (For a review of screening tools to assess trauma and its effects, see (119–120).)

Assessment of risk factors deserves special attention. Information should be gathered concerning the child's past functioning (traumatic/stressful experiences such as divorce, hospitalization, birth of a sibling, mental and general health problems) as well as disaster-related events (personal injury, loss of loved ones, witnessing severely injured or dead people, separation from parents, experiencing hunger or lack of sleep). A risk index may prove a useful guide in identifying symptomatic children as well as those requiring special attention (35,64,77,93,121). During screening, mental health professionals should create trusting relationships with parents to enhance commitment and facilitate recovery (122).

CHILD MENTAL HEALTH INTERVENTION PRINCIPLES: THE

SYSTEMIC PERSPECTIVE

Mass disasters have an impact on children through the entire sociocultural milieu (20,58,70). To manage this complex challenge, interventions must be formulated from an integrative perspective, focusing on maximizing well-being, self-efficacy and return to normalcy, and minimizing stress and disorganization. Such interventions must help victims find meaning and instill a sense of control without interrupting individuals' and communities' natural processes of resilience (21).

In their approach to public mental health, Pynoos et al. (17) emphasized the need to resolve institutional conflicts over authority and resource allocation, to address teachers' own disaster experiences, and to properly select and train intervention teams to work with severely traumatized victims. Population screening is useful to pinpoint areas that require specific resources and government support.

The effect of mass disasters is extremely devastating because of the concomitant loss of sociocultural regulators, leading to the destruction of basic schemes, values, roles, and structures (family and individual), and leaving the community vulnerable to pain, grief, trauma, and anger. Working in such a milieu, professionals may find themselves embroiled in confusion and red tape from the various social/government systems (medicine, education, welfare, nongovernment organizations [NGOs]) and the intervention teams trying to help. Therefore, a systemic perspective is needed to clarify the picture and to help psychiatrists (a) formulate the newly established needs of child-oriented institutions, (b) transfer knowledge and empower professionals in related fields to resume their role, (c) define their own role and carry out specific interventions, and (d) be familiar with the system within which they operate.

Mental health interventions for children and families exposed to mass disaster should follow the five AREST principles. Specific implementation of these principles will differ according to the particular characteristics of each country (19):

Anticipate: Interventions should provide an integrated vision, foresee different scenarios, and include contingency plans. Professionals and paraprofessionals must be trained, human and economic resources appropriately allocated, and treatment protocols created and exercised. For example, although 95% of 2,137 schools sampled in the United States have emergency evacuation protocols, 30% of them have not practiced them even once (123). Efficient local, national, and international networks need to be developed, including collaboration among agencies (education, police, health), clear command and control chains and communication channels, and the establishment of sponsorship and legitimacy (124).

Redifferentiate: Child psychiatrists should identify the extent of social loss in terms of institutional and role dysfunction. They must plan the process of context-related redevelopment of professional roles within and between systems (health, welfare, education) with the help of multidisciplinary teams. Particular attention

should be addressed to reconstituting the roles of parents and teachers.

Empower: Child psychiatrists need to debrief (if necessary), educate, and empower social agents (e.g., teachers) who are in direct contact with children to serve as mental health mediators. They must help these agents restore and adapt their original roles, and delegate some therapeutic responsibilities to them, supplying them with professional vision and positive expectations.

Supervise and Assess: Psychiatrists should define boundaries, provide knowledge, expertise and support to therapeutic agents, assess program development, and identify needs by feedback mechanisms. As leaders, mental health professionals need to encourage creative initiatives among team members and provide them with individualized consideration.

Treat and Follow-up: Treatment focuses on the rehabilitation of individuals and families. Delayed responses should also be considered.

At times of disaster, the priority is basic survival. Safety, shelter, and food, the most immediate and conspicuous needs, are usually within the domain of professional relief teams. Yet team members may themselves suffer from role-related problems because of the disaster-induced collapse of their familiar sociocultural matrix. Therefore, mental health professionals in positions of authority must respond to these needs, both within their own team and in the teams in which they act as mediators (e.g., teachers, school counselors). They must make team members feel cared for and help them develop a sense of belonging and purpose (125).

The ongoing operation of mental health interventions after disasters requires the constant commitment of professionals, leaders, and local agencies. By endorsing a systemic perspective, mental health professionals may overcome repeated adversities and challenges, inadequate professional training, limited resources, and organizational conflicts that tend to characterize the process.

Because parents and teachers tend to underestimate the extent of children's suffering (39), and given that disaster survivors are also often reluctant to seek professional help (126), systematic *outreach* efforts should be made to screen victims at risk. Optimally, this screening should take place 1 to 3 months after the disaster (127). Thereafter, clinical triage protocols can be utilized to match risk groups with intervention programs (15,72,127).

The first step in implementing such programs is to train members of the affected community. The local staff may need constant support and supervision. Such a process may help reduce the ambivalent resistance of traumatized survivors to what might be perceived as a foreign "intrusion" that threatens the "trauma membrane" protecting them from an overload of psychic tension (15,127).

INTERVENTION MODELS

Several issues need to be considered when implementing psychological interventions (20): timing (utilizing a sound, evidenced-based intervention at the wrong time could prove ineffective and harmful); whether the intervention is too intrusive; the empirical support regarding the intervention's effectiveness (20,21); the potential tampering with natural resilience processes (poor implementation of interventions might hinder resilient individuals' ability to recover naturally); and cultural congruence.

Treatments for children in the aftermath of disaster should protect and rehabilitate the secure base of attachment and meaningful relationships, support normalization, and train first responders, including parents and teachers, on relevant developmental issues (68,93). Child intervention programs should aim to restore damaged communal institutions and norms as well as communal functioning (to reclaim communal roles: parent, teacher, worker, leader). In circumscribed mass disasters, effective programs may take 12 to 18 months.

Preparedness Interventions

Disaster preparedness interventions such as training first responders, assigning responsibilities to organizations and improving their communication are of great value (68,88). A plan should be instituted for reuniting families and for maintaining the functionality of all systems, with emphasis on keeping normal routines intact (19,20). Perry and Lindell (128) recommended that preparedness programs be based on accurate knowledge of the threat and of probable responses, encourage appropriate action by emergency personnel, emphasize response flexibility, address inter-organizational coordination, and practice drills.

Appropriate preparedness of a city/country can significantly reduce the consequences of a disaster. For example, the Urban Resilience Program (URP) was implemented in 18 Israeli cities. The URP is based upon special interest in child social services to engage leaders, institutions, and communities to motivate the entire community. The model also recognizes the value of identifying opportunities emerging from communities' failure to meet basic human service needs. As such, the URP focuses on recreating social capital by reconfiguring the relevant human services, so they are accessible and able to provide further training to help the individual, the community, and the system cope with the event. The URP is based on four interrelated resilience components: health and mental health, information, population, and education.

1. Health and mental health resilience are addressed by bestowing the responsibility for these domains under unified and well-controlled municipal coordination. Each city establishes a health headquarters to coordinate emergency medical operations and to integrate community and public health institutions, general and mental health hospitals, as well as private health and

mental health agents.

2. Information resilience refers to citizens' urgent need for timely and reliable information that can reduce uncertainty, encourage preparedness, and increase coping among children, parents, families, and communities.
3. The population resilience component is directed at the urban municipality and its emergency preparedness systems, the city's institutional infrastructure, the local authority's psychosocial intervention system for emergencies, and the municipality's communities and inhabitants. The program offers leadership, training protocols, organizational guidelines, emergency simulations, and disaster drills for all urban dimensions, with specific attention to the needs of children and parents.
4. Education resilience is increased by developing teams to handle emergencies and implement preventive programs with children and parents in various educational child programs, from early infancy to adolescence, in collaboration with municipal and emergency bodies. Additionally, the program trains school psychologists as experts in trauma-related interventions and establishes a municipal educational headquarters to integrate between educational programs and security issues.

This model allows the development of a child-oriented URP that integrates all relevant child disaster services under a single command center. Data gathered over the course of 3 years show that the program has indeed increased cities' preparedness on all four components, as evidenced by enquiries conducted with department managers emphasizing actual execution of the program (129–131).

Indeed, the data show positive outcomes of preparedness interventions on risk reduction and resilience enhancement indicators (132). For example, children undergoing such programs frequently exhibit more preparedness knowledge (e.g., what to do in case of an earthquake), more discussions about hazards with others, and more preparedness activities.

Research on preparedness interventions points to four theory-driven ingredients that should be targeted (132): (1) help children increase their knowledge about disaster risk reduction (DRR); (2) encourage them to interact with others regarding their learning; (3) promote experiential activities aimed at DRR; and (4) provide DRR on more than one occasion.

Promoting these interventions at schools with an emphasis on school-wide and local emergency management agency support and providing teachers proper training can improve the chances for implementation (132).

Immediate Interventions—the Event through the First Few Weeks

According to contemporary reviews, interventions implemented immediately after

disasters (i.e., 0 to 3 months) should be handled with care, because intervening at this stage could be ineffective and also damaging (20,21). However, as Wang et al. (44) concluded in reviewing 85 studies regarding psychopathology among child disaster survivors, intervening at the early stages of disaster is vital since childhood pathology could have deleterious consequences later in life.

During the acute stage of disasters, the role of the mental health professional needs to be modified because of the limited number of professionals and the masses of individuals requiring help. Large populations need to be screened to identify children at risk. Other important tasks include initiating telephone crisis hotlines, supplying psychological first aid (PFA) for children and families in evacuation centers and hospitals, consulting authorities to assess immediate needs, and planning large-scale public health education programs. At this stage, professionals become aware of the need to acquire new disaster-related skills. Despite their experience with technically formulated protocol-based interventions, such professionals soon discover that mastering new therapeutic techniques and implementing them under disaster conditions require thorough training and ongoing supervision. Such skills can and preferably should be secured before proceeding with the intervention program.

In the following section, we present a brief summary of immediate intervention models and studies conducted to test their effectiveness. Note that studying interventions delivered in the acute aftermath of disasters is immensely challenging due to factors such as the urgency and chaos of the postdisaster environment, ethical concerns regarding withholding treatment and funding issues (21,133,134).

Critical Incident Stress Debriefing

Critical incident stress debriefing (CISD), a common practice of choice, consists of a single session designed to relieve trauma-related distress by providing people the chance to express thoughts and feelings, understand and conceptualize stress responses as normative under the circumstances, and learn about frequent trauma and disaster reactions in supportive settings. Despite the popularity of CISD, however, most studies have found it to be ineffective at best, if not harmful (20,21,134). Following the 2004 tsunami, the World Health Organization (135) recommended that it not be implemented.

Psychological First Aid

PFA is an evidence-informed program developed by disaster mental health experts. It is nonintrusive, applicable across many developmental levels, and culturally sensitive. PFA's focus is on promoting a sense of safety, connectedness, calming, self and community efficacy, and hope. It gives children the freedom to express feelings through storytelling and drawing and to identify areas of need. PFA is also helpful in

identifying individuals who may require further assistance. While PFA appears to be a promising component in immediate postdisaster interventions, it still lacks sufficient controlled studies (21,134).

Psychoeducation

Psychoeducation is also recommended, yet also lacks evidence as to its effectiveness. Brochures and fact sheets provide information regarding children's coping in the aftermath of disasters, and children's worries, fears, and security concerns in attempts to normalize their responses. Psychoeducation materials correct misinformation about disaster response and encourage children to express feelings and thoughts, while at the same time motivates them to reassume routine living (21,134).

To summarize, despite the lack of robust evidence the consensus seems to support a general mixture of PFA and psychoeducation materials as a means of action in an effort to assist children at this stage of disaster.

Second and Third Stage Interventions: First Few Weeks through Several Years Postdisaster

Saltzman et al. (136) proposed a public health approach consisting of a screening process and three tiers of mental health school- and community-based interventions after war and terrorism: general and broad-scale psychoeducational activities; manualized trauma/grief focused group psychotherapy for students at risk (see following); and highly specialized traditional treatments in the community for severely distressed and high-risk students.

Few intervention programs have been found to be effective in improving the condition of children survivors of disaster. All, to some extent, entail components taken from CBT (137), the most widely supported approach in this context (133).

The School Setting

Following mass disasters, professionals may need to work within a group format because providing individual assistance is less effective and generally impossible. Since teachers have already established relations of trust with children and parents, and most are ready to be educated and play a therapeutic role, intact school environments are appropriate societal recovery centers for interventions (124,138,139).

Therefore, schools could be utilized as primary settings for intervention with large numbers of children. Schools are familiar, safe places for children and help destigmatize treatment by mental health professionals (34), providing children

opportunities for peer support, constructive activities, leadership, self-efficacy, and relationships with competent adults (20). Getting back to normal routine, especially to school, is among the most protective factors against postdisaster pathology (20,68,140). Recommendations emphasize the need to restore the routine operations of schools, monitor the state of the children, supply consultation services to the entire school (including staff), train school faculty to answer children's needs, form support groups, and incorporate the disaster into the syllabus (140).

Teachers should allocate time to deal with traumatic experiences, model children's responses, reinforce emerging coping skills, provide factual information and dispel rumors, facilitate mutual support, identify suffering children, prepare the class for future experiences, and encourage students to become active contributors to their family, school, and community.

For a program to be effective, mental health professionals should ensure that the teachers (a) are not traumatized themselves; (b) are capable of mastering disaster-related educational techniques; and (c) have adapted their view of their role as teachers/educators in the new and harsh reality. To help regenerate the normal school setting after a disaster, the mental health professional needs to meet with teachers, help them process their own disaster experiences, and clearly describe the psychoeducational task at hand.

Based on these principles, Wolmer et al. (77) implemented a three-stage supervision program for the principal and teachers at one school after the 1999 earthquake in Turkey. First, a group session was conducted to normalize responses and enable expression of trauma-related affects (anger, guilt, helplessness, hopelessness). Then, an experiential activity was introduced to help teachers redefine their role *vis-a-vis* the students as educators and leaders. The authors stressed that in times of disaster, teachers were expected to maintain and enhance their role by providing individualized attention, transmitting values, and conveying positive expectations. As part of this role, they were taught to implement a disaster-related classroom activation program (see below). Finally, an ongoing supervision process was begun, led by local professionals, wherein teachers were not only educated but also provided support for each other (141).

Schools can provide excellent settings for preparedness interventions. Wolmer et al. (129) implemented such a program in Israel prior to rocket attacks during Operation Cast Lead. The study included 1,488 students from 12 schools, with half undergoing a 14-session teacher-led intervention 3 months prior to the attacks. Data gathered 3 months after the attacks showed that children in the nonintervention group exhibited more extreme symptoms and 50% more cases of PTSD compared to the study group.

School-based interventions include small-group programs and class activation programs.

Targeted *small-group programs* within the school setting may benefit high-risk

children or children who are more agitated and need closer attention than can be provided in the classroom (138,142). Smith et al. (143) formulated a three-session program to teach recovery techniques to small groups of children affected by disaster. The techniques used include psychoeducation, imagery and cognitive techniques, and exposure practice. Each session is dedicated to one domain of the posttraumatic syndrome: intrusion, avoidance, and arousal. The professional may also offer a fourth session for bereaved children and a session with parents, to provide them with information and suggest ways for them to help their children.

Class activation programs may vary in focus, scope, and depth, but all are intended to minimize stigma, encourage normalcy, and reinforce the expectation that the children will soon resume their roles as students (5,124,138). Nevertheless, because teachers themselves may be struggling with severe PTS and personal losses, they may feel unable to help their students. Some may try to avoid dealing with reminders of the event by stressing that children have no need to talk about their traumatic experiences (17).

The teacher-led class activation described in Wolmer et al. (77) began with an initial meeting with the parents to provide information about the program and the children's expected reactions to the disaster and to engage them in the process. The subsequent eight 2-hour meetings of the whole class focused on various aspects of the recovery process (e.g., establishing a safe place, learning about the earthquake, loss and death, dealing with anger, planning the future). The program combined psychoeducational modules, cognitive–behavioral techniques, play activities, and ongoing documentation in personal diaries. The program yielded immediate reductions in PTS and dissociation symptoms. In addition, a 3-year controlled follow-up study showed that children who had participated in the intervention adapted better than nonparticipants in terms of academic, social, and behavioral functioning (144).

CLINICAL INTERVENTIONS

Individual Interventions

Although group interventions are efficient and cost effective, they may not be sufficient for those children who are most affected. Controlled and uncontrolled studies have confirmed the effectiveness of brief cognitive–behavioral treatment in traumatized children (133,145). Other modes have been employed, such as play therapy and psychodynamic psychotherapy, as well as trauma-focused CBT (146). Recently prolonged exposure therapy, including psychoeducation about trauma, recounting scenes from the traumatic events, and in vivo exposures to associated feared stimuli and triggers, has been adapted to toddlers and their parents (147). Particular attention should be directed to prior and current comorbid pathology, as

well as to a thorough differential diagnosis (e.g., mania, ADHD).

Another approach is eye movement desensitization and reprocessing (EMDR) (148), devised to process distressing memories by having the child focus simultaneously on the disturbing memory and on a therapist-directed attention stimulus. Although studies on EMDR are scarce and additional research is needed to determine its effectiveness in treating disaster survivors, some evidence exists to support its implementation (149). Another mode of individual intervention involves exposure techniques, often incorporated with relaxation and breathing techniques. In vivo exposure highlights encountering feared stimuli associated with the event, while in vitro exposure highlights mastering traumatic memories (133). Research examining these techniques has yielded data in support of them (e.g., influencing test anxiety and academic performance (150)), yet more study is needed to further validate their efficacy.

Goenjian et al. (141) implemented a brief treatment program combining classroom group psychotherapy and individual sessions that focused on trauma and grief. The sessions, led by therapists, allowed for open discussion of traumatic experiences and associated feelings, assisted the children in solving intra- and interpersonal problems, and offered effective cognitive–behavioral techniques to manage thought distortions, disturbing images, and stress-related sensations. Five years after the event, the PTS of treated adolescents had decreased more significantly that those of untreated adolescents (5).

Group Interventions

Parent–Child Groups

Families have the potential either to protect children and mitigate their postdisaster suffering or to jeopardize how they adjust to and process the event. After disasters, children and parents tend not to discuss their distress, probably to avoid upsetting each other further (7). Yet studies show a significant association between the symptomatic response of children and their parents (particularly their mothers) (10,31,94), which may in turn have a traumatic impact on the parent–child dyad (59).

Based on previous successful application of parent–child group psychotherapy in treating child anxiety disorders (151), and as a second stage of class activation, Laor et al. (106) formulated an eight-session protocol for mothers and children with chronic PTSD. The group addressed dynamic, cognitive, and behavioral aspects of the disaster syndrome, and offered techniques to manage anxiety, relieve, control and transform distressing affects, correct thought distortions, and plan for the future. Special attention was paid to identifying and correcting maladaptive family dynamics and helping mothers and children recover their attachment and roles. Preliminary clinical and empirical results showed significant symptomatic alleviation as well as

a dramatic improvement in familial communication and mutual support.

Mothers' Groups

Group interventions with mothers facilitate indirect focusing on preschool children, a population that may not be reached in formal settings, yet can display maladaptive behavioral reactions. Providing structured therapeutic interventions, psychoeducation, and practical suggestions for the children as well as strengthening participants' confidence in their maternal role are important objectives for such groups (152).

POST-DISASTER COMMUNITY-BASED INTERVENTIONS

Disasters affect entire communities, threatening social structures and functions. To be effective, interventions require collaborative efforts among NGOs and formal and informal agencies. Developing a local leadership of committed individuals and empowering these leaders to actively meet the short- and long-term needs of the community provide a valuable source of support (153). If interventions are intended to rebuild and enhance collective resilience, specific efforts need to be made for communities to develop financial resources, minimize resource disparity, and pay special attention to socially vulnerable sectors. Moreover, the local population, including children (140), should be integrated in the planning and execution of such interventions, and connections between different organizations need to be formed. Furthermore, natural social support needs to be enhanced, decision-making and problem-solving abilities need to be developed, and reliable sources of information need to be maintained.

Child psychiatry relief programs need to respond to disasters on three levels: (a) *The family.* Families may suffer from injury, loss, or death of loved ones; relocation and unemployment; loss of boundaries, routine, and values; and loss of esteem and hope. (b) *The neighborhood.* Neighborhoods are subject to physical and economic destruction, loss of routines, boundaries and safety, disintegration of informal networks, and restriction of leisure time activities. (c) *The community.* Communities suffer from a lack of proper leadership and resources, frozen initiatives, dependence on external resources, destruction of social and cultural institutions (schools, community centers, religious centers) and, as a result, a foreshortened sense of a communal future.

Through auxiliary social functions and structures introduced from the outside, as well as through professional clinical and social teams, temporary communities of displaced population can be helped to gradually develop coping and functioning mechanisms. The goal of community-based intervention is to transform evacuated fragments of families and singletons into self-governing communities made up of

autonomous individuals and families (16). Since children cannot be fully rehabilitated until their parents resume working and regain income, professionals may also help facilitate the creation of new job resources in the community.

Using the intervention principles described above, child mental health professionals together with child community workers and local leadership can help set up community center programs for young mothers, children, and adolescents. Programs for empowerment and enhancing resilience may include the arts, sports, gardening and decorating, continuing education, job clubs, and volunteer recruitment and training in different areas (154). By *empowerment,* we mean a process of involvement through which individuals and communities supplant their helpless stance by recovering their dignity and self-esteem, enhancing their critical self-awareness, gaining control over resources and objectives, and regaining a sense of personal and collective responsibility and self-efficacy (152,153). Individuals are able to identify specific needs and discover hidden leadership qualities, while communities gain a greater sense of interdependence, cohesion, and cooperation. Professionals may take part in modifying the school curricula to address group mourning and resilience, collective memorials, as well as celebrations of rebirth. The juxtaposition of commemoration and rebirth ceremonies helps individuals gain new meaning in life in the face of profound mourning and leads to integration on both the personal and the communal levels, thus offering children an uninterrupted supportive matrix.

PHARMACOLOGIC INTERVENTIONS

Psychotherapy is widely considered the first-choice treatment for posttraumatic states (155). However, some pharmacologic interventions do exist, though they lack empirical support (137). Nonetheless, reduction of even one disabling symptom (insomnia, hyperarousal) may have a positive ripple effect on a child's functioning (156).

Even in the early stages of intervention, medications can be administered to children with a history of psychopathology; to individuals who do not respond to short-term specific interventions; and to members of families at risk that are overwhelmed by acute symptoms. Medications can be directed at specific symptoms, such as intrusion, hyperarousal and impulsivity (e.g., clonidine), anxiety (SSRIs, benzodiazepines), depression (SSRIs), psychotic symptoms, or severe aggression (antipsychotics) (155).

In a comprehensive review, Donnelly (156) proposed that broad-spectrum agents such as SSRIs are a good first choice because they are effective in treating the core symptoms of PTSD and comorbid symptoms (depression, anxiety). Furthermore, the antiadrenergic agents prazosin and clonidine, the mood stabilizer carbamazepine, and possibly the second-generation antipsychotics risperidone and quetiapine can be

helpful, though further investigation is necessary (157,158).

DISASTER RESEARCH

While disaster research is of utmost importance, it is extremely hard to carry out. Most disasters occur unexpectedly, and even those that are predictable have such an overwhelming impact that they exhaust all professional and economic resources. Furthermore, even when professional curiosity is maintained, assessment measures are enlisted, and questions are defined, implementation of such research is met by resistance on the part of both victims and clinicians. Research under such conditions tends to be perceived as hostile, foreign, exploitative, and abusive, and intended to satisfy an alien agenda that is irrelevant to the priorities of disaster relief. These claims have a kernel of truth: The hands that pass out the questionnaires could have been offering bread instead.

Other challenges have contributed to the scarcity of high-value disaster research (20,21,68,133). Apart from the aforementioned issues, disasters cause major devastation and conditions could be dangerous and chaotic, with no research infrastructure. Most disaster research lacks predisaster data. Additionally, it is not easy for researchers to receive funding for such projects, for most funds are logically directed to basic needs such as housing, food, and the like. Moreover, researchers do not always have culturally suitable tools, or are unable to secure good comparison groups (whether due to ethical or pragmatic concerns). In addition, follow-up data are extremely hard to gather and most studies fail to identify the active components of seemingly effective programs.

Research initiatives should be integrated within the systemic intervention program and should rely on direct assessment of the affected population at every stage. In this way, real risks and needs can serve as a basis for rational planning as well as for improvement of existing programs. Professionals are responsible for educating community leaders to take practical advantage of assessment data.

The scene of a disaster as a large-scale natural experiment offers access to communities that constitute different types of research groups and controls. Furthermore, each community may include a large number of entire families whose members were simultaneously exposed and affected in different manners (direct/indirect) and degrees, and for different lengths of time, as well as individuals suffering from losses of varying severity. An important issue in studies of children is the phenomenology and biologic susceptibility to the disaster syndrome, that is, the interplay of traumatic grief, PTS, and dissociation with psychoneuroendocrinologic and psychophysiologic parameters. This particular setting provides a unique opportunity for genetic studies. Special attention also ought to be directed at partial and delayed-onset types of disorder, as well as concurrent psychiatric and medical morbidity.

Another area of interest is the control study and the comparative effectiveness of various interventions, as well as assessment of parameters of community resilience and vulnerability, the long-term sequelae of disaster in terms of the developmental psychopathology of high-risk populations, the transgenerational transmission of trauma and grief, and the development of sociopolitical attitudes. Nevertheless, the search for answers to these questions cannot violate the privacy of the children being studied, and clinicians must be careful to comply with accepted ethical guidelines. Institutional review boards can facilitate the process by offering a fast track for disaster-related research proposals.

CONCLUSIONS

Disasters destroy the space within which children and families thrive, thereby disrupting normal development. The overwhelming nature of such events, combined with the massive extent of the resulting loss, gives rise to a complex clinical and social picture that may be termed the disaster syndrome. Children, families, neighborhoods, and whole communities are affected. Immediate damages can only be partially remedied, and therefore the physical, psychological, and social effects are long lasting.

For effective intervention, child mental health professionals should adopt a comprehensive systemic, social, and mental health perspective in order to develop the appropriate program, team up with the proper authorities, proactively assess needs, and implement intervention based on real-time integrated information systems. The best results can be achieved when communities are prepared. Some interventions are clinical and specific. They may be mediated by educated professionals who work with children in schools and community centers. Other interventions are systemic.

The systemic concepts and principles presented in this chapter (159,160) are reflected in the congressional report investigating the preparation for and response to Hurricane Katrina (161). As the report demonstrates, even when enormous resources are allocated, if authorities do not adhere to theoretical, organizational, and implementation principles of disaster management, disasters exact colossal consequences.

No single community can cope on its own, for adequate coping requires advanced networking on the local, national, and international levels (162). Resilience built on these levels of organization constitute the social capital available to individuals and communities to withstand and recover from disaster (163). Thus, the challenge posed by disasters can be met by our vision of the siblinghood of humanity. A global community committed to children must respond to the challenge.

SECTION VI

TREATMENT

6.1 PEDIATRIC PSYCHOPHARMACOLOGY

CHAPTER 6.1.1 ■ NEUROCHEMISTRY, PHARMACODYNAMICS, AND BIOLOGIC PSYCHIATRY

GEORGE M. ANDERSON AND ANDRÉS MARTIN

INTRODUCTION

Continuing advances in basic neurobiology and psychopharmacology have led to a greatly expanded knowledge of brain functioning and hold the promise of better treatment and fuller understanding of childhood psychiatric disorders (1,2). The recent elucidation of the genetic bases of a number of single- gene childhood psychiatric disorders provides additional hope, and to some extent directions, for tackling the more complex molecular and biologic influences in autism, attention-deficit hyperactivity disorder (ADHD), Tourette syndrome (TS), anxiety, posttraumatic stress disorder (PTSD), depression, and suicide. Identification of causative factors in Parkinson's disease, Huntington's disease, and Alzheimer's disease further encourages the notion that the pharmacology of childhood psychiatric disorders can be made more rational and effective, and the biologic bases of the relevant behaviors ascertained.

The three entwined areas of neurobiology, pharmacodynamics, and biologic psychiatry can be introduced by first considering the basic concepts in the separate realms of inquiry. Relevant neurobiology includes findings in the areas of neuronal circuitry, neural transmission, and intracellular signaling. Pharmacodynamics concerns the short- and long-term effects of drugs on neuronal function and structure. Insights and serendipitous findings from psychopharmacology reciprocally inform basic neuroscience and also have often been central to the hypotheses pursued in biologic psychiatry. Recognition of the importance of genetics and complexity of psychiatric disorders is changing in fundamental ways how biologic psychiatry is approached. Whether the field is termed molecular psychiatry, biologic psychiatry, or clinical neuroscience, an increased focus on genetic influences and on behavioral components or endophenotypes has been prompted by a better appreciation of the scope and complexity of the endeavor.

GENERAL CONSIDERATIONS OF CNS FUNCTIONING

Overview

Neuronal circuitry, synaptic neurotransmission, and intracellular information processing constitute three major levels of central nervous system (CNS) functioning

critical to understanding mechanisms of psychotropic drug action and the biologic basis of cognitive and behavioral processes.

Neuronal circuitry to a large extent defines and reflects the functional activity and organization of the CNS. Neuronal communication via neurotransmitter release is a fundamental mechanism of brain function. The release of neurotransmitters and neuromodulators, their mechanisms of action, and their effect on target neurons are complex and still not fully understood; however, despite the diversity of neurotransmitters and receptors in the human brain, all forms of neural communication have the common goal of modulating neuronal activity. This is achieved by changing either the electrical or biochemical properties of the cell. The balance of intracellular and extracellular ions characterizes the electrical properties of the neuron. At rest, there are more negatively charged ions inside than outside the cell, thereby creating a negative resting membrane potential. Decreasing the resting potential leads to excitation, increasing it, to inhibition. The more enduring properties of the neuron are determined by longer-term processes regulating the expression of specific genes, the production of proteins, and the creation of a distinct metabolism.

Neuronal Circuitry

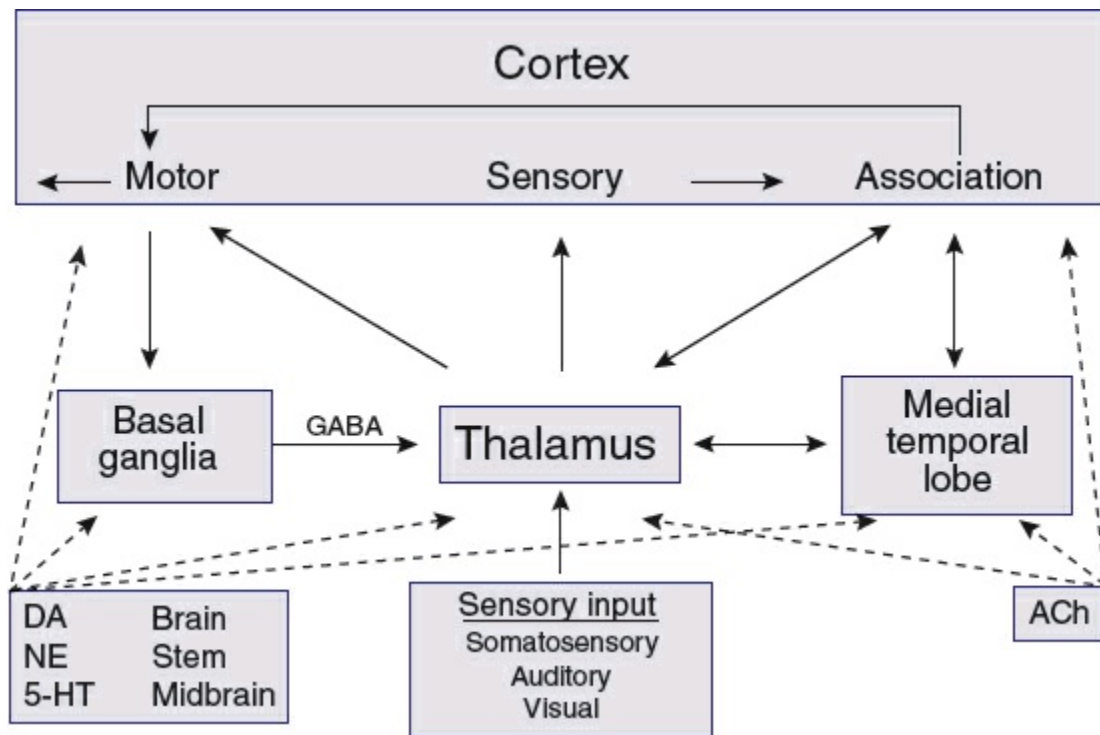
The adult human cerebral cortex has about 100 billion neurons; each neuron establishes about a 1,000 to 10,000 connections to other neurons. Neurons are arranged in distributed networks that play critical roles in the expression of human behavior (3). This involves the collection of sensory information through perceptual modules, the creation of a representation, and the production of a response. Here we focus on four major anatomic systems that are crucial for these three steps of information processing: the cortex, thalamus, basal ganglia, and medial temporal lobe (Figure 6.1.1.1).


FIGURE 6.1.1.1. Neuronal circuitry. Basic scheme of information processing in the human brain. *Straight arrows* indicate glutamatergic pathways. The BG–thalamus projection is GABAergic. The *broken arrows* indicate the widespread, neurotransmitter-specific projections arising from the basal forebrain (ACh) and brain stem (DA, NE, 5-HT). A1, primary auditory cortex; ACh, acetylcholine; BG, basal ganglia; DA, dopamine; 5-HT, serotonin; see text for further details.

1. The thalamus is the gateway to cortical processing of all incoming sensory information, here represented by the three major systems: somatosensory, auditory, and visual (Figure 6.1.1.1). Primary sensory cortices receive information from the appropriate input modules (sensory organ + thalamus).
2. The association cortex integrates information from primary cortices, subcortical structures, and brain areas affiliated with memory to create an internal representation of the sensory information.
3. The medial temporal lobe (including the hippocampus and amygdala) serves two major functions in the brain: to integrate multimodal sensory information for storage into and retrieval from memory, and to attach limbic valence to sensory information (e.g., pleasant or unpleasant, fight or flight).
4. The basal ganglia are primarily involved in the integration of input from cortical areas. The basal ganglia modulate cortical activity via a cortico-striato-pallido-thalamo-cortical (CSPTC) loop. The most prominent projections to the striatum arise from the motor cortex.

All major projections (solid lines) in this basic circuitry (Figure 6.1.1.1) are glutamatergic (using the amino acid neurotransmitter glutamate), except for the

projections from the basal ganglia toward the thalamus, which are GABAergic (employing γ-aminobutyric acid). The glutamatergic neurons within each of the major components or regions of the circuit are under inhibitory control by GABAergic interneurons. In addition, four groups of densely packed neurons provide diffuse projections to all areas of the brain to modulate their functions: cholinergic neurons in the basal forebrain and brain stem, dopaminergic neurons in the substantia nigra (SN) and ventral tegmental area (VTA), noradrenergic neurons in the locus coeruleus (LC), and serotonergic neurons in the raphe nuclei. The broken arrows in Figure 6.1.1.1 indicate the four neurotransmitter-specific projection systems. The relay of information from one neuron to another in these various circuits is usually affected by synaptic neurotransmission.

General Aspects of Synaptic Neurotransmission

Dendrites create a network of fibers providing the cell body of the neuron with input from other cells (Figure 6.1.1.2). The cell integrates these different inputs through modulation of the membrane potential, changes in second messenger systems, and at the level of the nucleus (regulation of gene expression). The cell body is also the site of synthesis of nearly all cell-specific proteins, including transporters, receptors, and the enzymes needed for neurotransmitter production.

The axon is the output station of the neuron. The axon can be short (local circuit neuron) or long (projection neuron). If a deviation from the resting membrane potential is above a certain threshold, an action potential is created and travels downstream rapidly. The nerve terminal is the widened terminal part of the axon. It provides a small area of close contact with dendrites of communicating neurons: the synapse. Variations of this typical scheme include synapses between two terminals, two dendrites, and neurotransmitter release in medial parts of the axon.

As seen in Figure 6.1.1.2, the presynaptic neuron releases the vesicular stored neurotransmitter into the synapse and can express two types of proteins that affect synaptic communication: Presynaptic membrane-bound receptors can bind the intrinsic neurotransmitter (at autoreceptors) or transmitters of neighboring neurons (at heteroreceptors) and affect the cell via intracellular messengers. One response, for example, is the modulation of neurotransmitter release (4). Presynaptic membrane-bound reuptake transporters pump the released neurotransmitter back into the cell (5). The released transmitter can undergo intracellular, extracellular metabolism (4B), or be repackaged in vesicules for rerelease.

The neuron receiving the input (postsynaptic cell) can be modulated via two different types of receptors (Figure 6.1.1.2). In the case of fast-acting, class I (ionotropic) receptors, the neurotransmitter binds to the receptor protein and within milliseconds, this leads to a change in the permeability of the associated ion channel, allowing the influx of ions such as Ca^{2+}, Na^{+}, K^{+}, or Cl^{-}. In contrast, with slow-

acting, class II (G-protein–coupled) receptors, the binding of the neurotransmitter to the receptor protein leads to a change in the protein conformation. This change is relayed to an associated G-protein, so called because it binds guanidine triphosphate (GTP) in order to be activated. G-proteins regulate two major classes of effector molecules: ion channels and second messenger generating enzymes. This general pattern and form of synaptic neurotransmission is repeated across the six major neurotransmitters. However, the differences seen across the glutamatergic, GABAergic, dopaminergic, noradrenergic, serotonergic, and cholinergic systems are intriguing, form the bases of specific psychopharmacologic effects, and underlie still prevailing neurobiologic theories of biologic psychiatry.

INTRACELLULAR INFORMATION PROCESSING

Our understanding of how neurons relay information between each other has moved beyond the role of synaptic transmission and into that of processes that take place within cells. Each neuron is the target of many projections from local and distant neurons. These influences are integrated at the level of the cell membrane and cell nucleus. The neurotransmitter-mediated activation of ion channels in the cell membrane can lead to an increase or decrease of the resting membrane potential. This may lead to the creation of an action potential. At the level of the cell nucleus, the various receptors and ion channels expressed on the cell membrane may influence gene and protein expression.
FIGURE 6.1.1.2. A: Anatomy of the neuron with major aspects of typical pre- and postsynaptic neurons labeled. Also depicted are six major mechanisms of synaptic neurotransmission: (1) release of

neurotransmitter stored in vesicles; (2) binding of transmitter to presynaptic autoreceptor; (3) clearance of transmitter by reuptake; (4) A-intracellular metabolism of transmitter, B-extracellular metabolism of transmitter; (5) binding of transmitter to G-protein–coupled receptor; (6) binding of transmitter to ion channel coupled receptor; see text for details. **B:** Intracellular information processing. Neurotransmitters released from the presynaptic neuron activate receptors at the postsynaptic neuron. Second messengers either enter the neuron (e.g., Ca^{2+} through ligand-gated ion channels) or are newly synthesized inside the neuron (e.g., G-protein–coupled receptors stimulate adenylate cyclase and the synthesis of cyclic AMP). Neurons usually have multiple receptor types and are able to integrate information from a variety of synaptic inputs. Second messengers stimulate protein kinases and protein phosphatases to control the state of phosphorylation of various proteins inside the neuron. Transcription factors such as CREB are regulated by kinases and phosphatases. A high level of discrimination is observed, although some transcription factors integrate information from different second messenger pathways. Thus, kinases and phosphatases regulate groups of genes under the control of specific transcription factors. **Inset:** Phosphorylation of CREB stimulates the transcription from DNA into RNA, which is transported out of the nucleus and translated (with ribosomes and tRNA) into protein.

Gene expression is regulated by transcription factors that bind to specific sequences of the DNA in the nucleus (Figure 6.1.1.2B); therefore, membrane-bound receptors or ion channels in distal parts of the neuron must be able to activate intraneuronal signal transduction pathways that can span long distances and translocate to the nucleus. Because proteins assemble the neuron and determine neuronal properties, gene expression regulates neuronal function and may cause malfunction. Many psychopharmacologic agents with delayed therapeutic effects are thought to produce their therapeutic benefits through modulation of gene expression (6,7).

Release of neurotransmitters from the presynaptic neuron into the synapse activates receptors on the postsynaptic neuron (see Figure 6.1.1.2B). Ions such as calcium enter the cell and act as second messengers on activation of inotropic receptors. Activation of G-protein–coupled receptors facilitates the opening of neighboring ion channels or the synthesis of second messengers such as cyclic AMP. Second messengers (calcium, cyclic AMP) regulate the activity of protein kinases (proteins that transfer phosphate groups to a substrate protein) and phosphatases

(proteins that remove phosphate groups from a substrate protein). In all cases investigated to date, the activation of neurotransmitter receptors changes the state of phosphorylation of neuronal proteins.

The transcription factors are one group of proteins regulated by phosphorylation. Transcription factors operate by recruiting the transcription initiation complex and RNA polymerase to particular genes. The RNA polymerase then transcribes the DNA template into an RNA molecule, which is translated into protein outside the nucleus.

Among the best-studied transcription factors in the brain is the Ca^{2+}- and cyclic AMP-responsive element binding protein (CREB). The study of CREB has provided us with an insight into the complex consequences of transcription factor activation and gene expression on higher brain function. A variety of signal transduction pathways are integrated into CREB-mediated gene expression, such as those activated by Gs-proteins, inotropic receptors, or growth factors. Cyclic AMP-responsive element binding protein is activated by phosphorylation and regulates the expression of several target genes (e.g., genes for peptide neurotransmitters, enzymes involved in neurotransmitter synthesis, and growth factors). The discovery that CREB plays a vital role in processes such as learning and memory provided a link between gene regulation and cognitive function.

Small but persistent abnormalities in neurotransmission can have far-reaching consequences because neurotransmitters and receptors influence gene and protein expression in the brain. An understanding of signal transduction pathways and transcription factors such as CREB may be instrumental in providing new therapeutic avenues in psychopharmacology.

Pharmacodynamics Overview

Pharmacodynamic principles are concerned with the biochemical and physiologic effects of drugs at their active sites, that is, with their specific mechanisms of action. Stated succinctly, “pharmacokinetics describes what the body does to a drug; pharmacodynamics what a drug does to the body” (see Chapter 6.1.2 (Oesterheld, Shader, & Martin)). The effects of a medication may change during development, as brain regions or neurotransmitter systems develop and mature. Most psychopharmacologic agents exert their effects by interacting with specific protein targets—receptors, ion channels, transporters, or enzymes. Each of the major neurotransmitter systems has, therefore, a number of routes by which they can be manipulated (as are delineated in subsequent sections). The nature of the drug effect depends upon the site targeted while the selectivity of action is often a function of the relative affinity of the agent for the target site versus its other, often multiple, sites of interaction. Adverse drug effects are often the result of relatively nonselective agents and can severely limit their clinical utility.

Biologic Psychiatry Overview

Research in biologic psychiatry has made it increasingly clear that the genetics and biology of the common disorders are complex, in that multiple genes appear to contribute to the syndromes (Chapters 3.3.2 (Fernandez, Gupta & Hoffman) and 3.3.3 (Tomasi, Lennington, Leckman, & Lombroso)). This is not surprising given the complex and diffuse nature of the neural systems that subserve the relevant brain processes (8). The genetic complexity is further multiplied by the wealth of variation arising from gene–environment interactions: Illuminating the complexity will require the application of new and appropriate genetic methods (9–11).

An emerging overarching theme is that all biologic, neuropharmacologic, and behavioral investigation needs to be performed in a genetic context. There is also a greater focus on components or domains of behavior and a greater interest in quantifying the traits or variables of interest. The rationale for examining what have been referred to as elementary units of psychological dysfunction (12), core or candidate symptoms, quantitative phenotypes (13), endophenotypes (14), or core psychopathologic processes (15,16) is becoming more and more compelling.

One formulation of the interrelated aspects of biologic psychiatry is presented in Figure 6.1.1.3. The mutual interacting influences of genetic and environmental factors are shown determining the neurobiologic systems that, in combination, form the substrate of relevant behaviors. The field of biologic psychiatry has traditionally emphasized neurochemical and neuroendocrinologic approaches. Other fields and approaches that are now proving critical to advancing an understanding of brain neural transmission in psychiatry include neurophysiology, neuropsychology, neuroimaging (17) pharmacogenetics (18), and network analysis (19). Elucidation of the bases of the childhood disorders can be expected to proceed through an iterative process involving mutually beneficial relationships among all of the perspectives (20). It is clear that one should be ever mindful of the developmental context when studying childhood psychiatric disorders (21,22).

The mutual interacting influences of genetic and environmental factors are shown determining the neurobiologic systems that combine to form the substrate of relevant behaviors. The behaviors can be assessed through a range of measured phenotypes (**A–C**). The multiple behavioral components of most syndromes and disorders are depicted by the receding additional behavioral components (1–3).

NEUROTRANSMITTER SYSTEMS

Overview

The major neurotransmitter systems can be divided into two groups based on their anatomic distribution. The first group comprises the serotonergic, dopaminergic, noradrenergic, and cholinergic neurons. These four systems originate from small

groups of neurons, densely packed in circumscribed areas of the forebrain or brain stem, and project to their target areas typically by long-ranging projection fibers. The second group includes the glutamatergic and GABAergic systems. Their neurons are by far the most prevalent and widely distributed types in the human brain. As mentioned, a number of similarities and parallels are apparent across the neurotransmitter system. Each system will be considered from the standpoint of its anatomy and neural transmission mechanisms, its pharmacodynamics or psychopharmacology, and the relevant biologic psychiatry investigation.

SEROTONERGIC SYSTEM

Serotoninergic Neural Transmission/Neuroanatomy

Most serotonergic cells overlap with the distribution of the raphe nuclei in the brainstem. A rostral group (B6–8 neurons) projects to the thalamus, hypothalamus, amygdala, striatum, and cortex (23). The remaining two groups (B1–5 neurons) project to other brainstem neurons, the cerebellum, and the spinal cord. A schematic diagram of a serotonergic neuron and the metabolism of serotonin (5-HT) are depicted in Figure 6.1.1.4. Serotonin is produced after hydroxylation and decarboxylation of the essential amino acid tryptophan. Serotonin produced can be taken up by the vesicular monoamine transporter (VMAT2) and stored in vesicles for subsequent release or metabolized by the mitochondrial enzyme monoamine oxidase (MAO). Once released, 5-HT can interact with presynaptic or postsynaptic receptors, diffuse to extrasynaptic sites, or be taken up by neuronal or glial membrane 5-HT transporters (5-HTTs).

FIGURE 6.1.1.4. Serotonergic neurotransmission. Diagrammatic illustration of a serotonergic neuron. Serotonin (5-HT) synthesized from tryptophan (TRP) by the rate-limiting enzyme tryptophan hydroxylase (TRPOH) can be taken up by the vesicular monoamine transporter (VMAT2) and stored in vesicles for subsequent release or metabolized by the mitochondrial enzyme MAO. Released 5-HT can interact with presynaptic or postsynaptic receptors, diffuse to extrasynaptic sites, or be taken up by neuronal or glial membrane 5-HT transporters (5-HTTs). Inhibition of the 5-HTT by selective serotonin reuptake inhibitors (SSRIs) results in higher levels of synaptic and extracellular fluid 5-HT, leading to greater 5-HT

receptor stimulation.

Serotonin acts at two different classes of receptors: at an inotropic receptor (5-HT_3 receptor) or at slower acting receptors, coupled either to phospholipase C (5-HT_2 receptors) or to G-proteins (5-$HT_{1,4–7}$ receptors) (24). The 5-HT_1 receptors (5-$HT_{1A,B,C,D,E,F}$) (Figure 6.1.1.4) are coupled to G_i and lead to a decrease of cyclic AMP. The 5-HT_{1A} receptor is also directly coupled to a K^+ channel leading to increased opening of the channel. The 5-HT_1 receptors are the predominant serotonergic autoreceptors. 5-HT_2 receptors (5-HT_{2A-C}) are coupled to phospholipase C and lead to a variety of intracellular effects (mainly depolarization). Three receptors (5-$HT_{4,6,7}$) are coupled to G_s and activate adenylate cyclase. The 5-HT_3 receptor is the only monoamine receptor coupled to an ion channel, and is found in the cortex, hippocampus, and in the area postrema, where it mediates nausea and emesis. It is typically localized presynaptically and regulates neurotransmitter release.

Serotonergic Pharmacodynamics

Serotonin is linked to many brain functions because of the widespread serotonergic projections and heterogeneity of the serotonergic receptors (23,25). For example, modulation of serotonergic receptors and the reuptake site is beneficial (among others) in the treatment of anxiety, depression, obsessive–compulsive disorder, and schizophrenia (26). Interest in central 5-HT functioning derives from 5-HT's important role in processes as diverse and important as sleep, mood, appetite, perception, and hormone secretion (25), as well as its critical role in neurodevelopment (27).

Blockade of the serotonin transporter by selective serotonin reuptake inhibitors (SSRIs), such as fluoxetine (Prozac), results in higher levels of synaptic and extracellular fluid 5-HT and leads to greater pre- and postsynaptic 5-HT receptor stimulation. The serotonin transporter is the primary target site for several antidepressants, including the SSRIs, venlafaxine, and tricyclic antidepressants such as clomipramine and, to a lesser extent, imipramine and amitriptyline (Figure 6.1.1.4). Recent work in nonhuman primates has indicated that the increase in functionally active 5-HT occur within hours and is relatively constant over the course of treatment.

The atypical neuroleptics, such as risperidone, ziprasidone, and olanzapine, all act as antagonists at 5-HT_2 receptors, as well as having blocking properties at dopamine receptors. The beneficial antipsychotic effects of the drugs appear to be at least partly mediated through their effects at cortical 5-HT_{2A} receptors. In particular, it appears that 5-HT_{2A} receptors on apical dendrites of cortical pyramidal cells may

be especially important in gating sensory input. The critical role of the 5-HT_{2A} receptor in perception is underscored by a consideration of the effects of the 5-HT_{2A} agonist lysergic acid diethylamide (LSD). Adverse effects of the atypical neuroleptics on appetite and the associated weight gain appear to be at least partly due to effects at the 5-HT_{2C} receptor, while the substantial and enduring hyperprolactinemia frequently observed is a consequence of the dopamine D_2 receptor blockade in the pituitary.

Other serotonergic agents include the atypical anxiolytic buspirone, which acts as an agonist at the 5-HT_{1A} receptor. Newer antimigraine drugs such as sumatriptan have agonist effects at arterial $5\text{-HT}_{1B/D}$ receptors, while the antiemetic odansetron acts to antagonize 5-HT_3 receptor sites in the intestine and perhaps in the brain.

Biologic Psychiatry of Serotonin

Autism

Initial interest in a role for 5-HT in autism stemmed in part from the powerful effects of serotonergic agents, such as LSD, on perception. Research in the area was further stimulated by early reports of elevated 5-HT in the blood of autistic children (28,29). Beneficial effects of treatment with serotonin reuptake inhibitors (30) and exacerbation observed after tryptophan depletion (31) have also heightened interest in the role of 5-HT in autism. Although most of the 5-HT-related research has focused on the hyperserotonemia of autism, a number of studies of CSF 5-HIAA and several neuroendocrinologic studies of central 5-HT functioning have been reported (32). CSF studies are in general agreement that few or no differences exist between autistic and control groups' mean levels of 5-HIAA (33). A series of studies have provided converging evidence that 5-HT_{2A} receptor function and expression may be altered in autism. In 1989, McBride and colleagues (34) reported that central and peripheral 5-HT_{2A} receptor functioning appeared reduced in autism. Thus, a diminished 5-HT_{2A}-mediated neuroendocrine response was paralleled by a reduced 5-HT_{2A}-mediated platelet aggregation response and lower platelet 5-HT_{2A} receptor binding in autism. Alterations in platelet 5-HT_{2A} binding indices were also reported by Cook et al. (35), with 5-HT_{2A} receptor measures inversely related to platelet 5-HT levels. These reports are paralleled by two neuroimaging studies reporting reduced 5-HT_{2A} receptor density in cortical regions (36).

TS/OCD

A role for 5-HT has been hypothesized because of the close connection between TS and obsessive–compulsive disorder (37). Effective treatment of obsessive–

compulsive symptoms in patients with TS with the serotonergic uptake inhibitors, fluvoxamine and fluoxetine, has further stimulated research on the connection. The largest study of the 5-HT metabolite, 5-hydroxyindoleacetice acid (5-HIAA), found similar levels in patients with TS, OCD, or TS plus OCD, and the normal control group (38). No studies of 5-HT receptor functioning have been carried out in patients with TS, and early reports of benefit from the immediate 5-HT precursor, 5-hydroxytryptophan, have not been replicated. Research examining postmortem brain tissue has found decreases in 5-HT, 5-HIAA, and tryptophan across nearly all cortical and subcortical areas in TS (39,40). Further postmortem research is necessary in order to replicate the findings; however, the results tend to increase the possibility that 5-HT may be a factor in the symptomatology of TS.

Attention-Deficit Hyperactivity Disorder

Interest in a role for 5-HT in ADHD was stimulated by early reports of decreased platelet 5-HT in affected children. Subsequent studies have not replicated this finding and have found normal levels of platelet and urine 5-HIAA, as well as normal numbers and affinities of platelet imipramine-binding sites in subjects with ADHD. In addition, studies of CSF 5-HIAA have not found differences between ADHD and control subjects. On the whole, the neurochemical research and the minimal treatment response to serotonergic agents have made it seem less likely that a 5-HT alteration is etiologic. Even so, it appears that the role of 5-HT in disruptive behaviors, particularly with respect to impulse control, deserves further consideration.

DOPAMINERGIC SYSTEM

Dopaminergic Neural Transmission/Neuroanatomy

Dopaminergic neurons can be divided into three major groups based on the length of their efferent fibers: (a) ultra-short systems in the retina and olfactory bulb; (b) intermediate-length systems originating in the hypothalamus and projecting to the pituitary gland; and (c) wide-ranging systems originating from two areas, the SN and the VTA. The SN neurons (also called A9 neurons) project to caudate and putamen, whereas the VTA neurons (also called A10 neurons) project to limbic areas such as nucleus accumbens and amygdala (i.e., mesolimbic projections) and several cortical areas such as frontal, cingulate, and entorhinal cortex (i.e., mesocortical projections).

The metabolism of the catecholamine dopamine (DA) is shown in Figure 6.1.1.5. DA is synthesized from tyrosine, after hydroxylation to dihydroxyphenylalanine (DOPA) and decarboxylation by aromatic acid decarboxylase (AAAD), and is found in the highest concentration in the midbrain, although extensive cortical projections also occur. Dopamine has been shown to be critical in reward, modulating

movement, and cognition. Dopamine is released into the synapse from vesicles (Figure 6.1.1.5) and subsequently removed from the synapse by two mechanisms. First, catechol-O-methyl-transferase (COMT) degrades intrasynaptic DA. Second, the dopamine transporter (DAT), an Na^{+}/Cl^{-}-dependent neurotransmitter transporter, transports DA out of the synaptic cleft (Figure 6.1.1.5). Parenthetically, and of relevance to the action of stimulants, the transporter can actually function in either direction, depending on the concentration gradient. Free intracellular DA can either be taken back up into vesicles or metabolized by mitochondrial MAO.

Dopamine acts at two different classes of dopamine receptors in the CNS, the D_1 and D_2 receptor families (Figure 6.1.1.5) (41). The D1 receptor family includes the D_1 and D_5 receptors. Both are coupled to Gs (G-stimulating) and lead to an increase of cyclic AMP. The D_2 receptor family includes the D_2, D_3, and D_4 receptors. All are coupled to G_i (G-inhibitory) and lead to a decrease of cyclic AMP. There is a predilection of the different dopamine receptors for expression in specific brain areas (e.g., D_1 receptors are found in the striatum and cortex, D_2 receptors in the striatum and pituitary gland, and D_3 receptors in the nucleus accumbens). Presynaptic dopaminergic receptors are typically of the D_2 type and found on most portions of the dopaminergic neuron (as autoreceptors). They regulate DA synthesis and release, as well as the firing rate of DA neurons. Autoreceptors are 5 to 10 times more sensitive to DA agonists than postsynaptic receptors.

Dopamine affects several brain functions primarily by modulation of other neurotransmitter systems (42). Dopaminergic neurons of the SN project to the striatum and modulate the function of striatal GABAergic interneurons. Dopaminergic projections of the VTA to limbic structures such as the nucleus accumbens are known to be involved in reward behavior and the development of addiction to drugs such as ethanol, cocaine, nicotine, and opiates (43,44). Dopaminergic projections from the VTA to the cortex play a role in the fine-tuning of cortical neurons (i.e., modulation of signal-to-noise ratio) (45).

FIGURE 6.1.1.5. Dopaminergic neurotransmission. Diagrammatic illustration of a dopaminergic neuron. Dopamine (DA) synthesized from tyrosine by the rate-limiting enzyme tyrosine hydroxylase (TH) can be taken up by the vesicular monoamine transporter (VMAT2) and stored in vesicles for subsequent release, or metabolized by the mitochondrial enzyme monoamine oxidase. Released DA can interact with presynaptic or postsynaptic receptors. Inhibition of the DA transporter (DAT) by DA reuptake inhibitors (DAT blockers) results in higher levels of synaptic and extracellular fluid of DA and leads to greater DA receptor stimulation.

Dopaminergic Pharmacodynamics

Dopamine receptor blockade, particularly at D_2 sites in the frontal cortex, is a major mechanism of action of most antipsychotic drugs (Figure 6.1.1.5). Both the older typical neuroleptics like the phenothiazines (e.g., chlorpromazine) and butyrophenones (e.g., haloperidol), as well as newer atypical neuroleptics including risperidone, ziprasidone, and olanzapine, have antagonist effects at D2 receptors. The most recently introduced atypical antipsychotic drug, aripiprazole, appears to work by serving as a partial agonist at both pre- and postsynaptic dopamine receptors. By so doing, aripiprazole may moderate dopaminergic function, reducing presynaptic dopamine release while modestly stimulating postsynaptic receptors.

Dopamine is released into the synapse from vesicles (Figure 6.1.1.5) and this process is facilitated by the stimulants methylphenidate and amphetamine. Stimulant drugs such as amphetamine and cocaine also potently block the DAT. The euphoriant properties of the stimulants appear to be principally mediated through their enhancement of dopaminergic transmission in the striatum (specifically, the nucleus accumbens).

Biologic Psychiatry of Dopamine

Attention-Deficit Hyperactiviy Disorder

The symptomatology of ADHD includes inattention, distractibility, and impulsivity, with or without hyperactivity (46). The remarkable effects of stimulants on children with ADHD have led to a longstanding and continuing interest in the role of DA. Family and twin studies have strongly supported the idea that there are inherited components to the disorder (47).

A large number of neurobiologic studies have been carried out; the majority involves the measurement of neurotransmitter metabolites in blood and urine, either at baseline or after pharmacologic perturbation. An increasing number of brain imaging studies have been reported (48). These studies have tended to focus attention on the frontal cortex and midbrain DA nuclei and their projection areas. The well-replicated genetic findings of an association between ADHD symptomatology and alleles of the DAT and D4 DA receptor genes (18) have further increased interest in DA. Although the neurochemical investigation has been extensive and includes studies of dopamine and its principal metabolite, homovanillic acid (HVA), in CSF, plasma, and urine, it has failed to establish definitive alterations in ADHD. Neuroendocrine studies in ADHD are limited and also provide no definite information regarding possible group differences.

Tourette Syndrome

Neuroanatomic and neuropharmacologic considerations have prompted a number of neurochemical studies with a focus on the monoamines DA, 5-HT, and NE in TS (49,50). A role for DA is suggested by the amelioration of tics by neuroleptics, exacerbation of symptomatology after administration of stimulants, and importance of DA pathways in modulating basal ganglia output (51). The measurement of the DA metabolite HVA in CSF has not revealed consistent differences between mean levels in TS and control groups (38). Studies of postmortem brain from a small number of patients with TS have yielded conflicting results. Singer and colleagues (50,52) have found increased densities of the DA transporter in basal ganglia regions and suggested that the increased densities are a reflection of increased DA innervation within the striatum; however, observations of the normal striatal levels of DA, HVA, and tyrosine hydroxylase do not support this idea (39,40). Although an initial imaging study reported higher striatal DA transporter binding in Tourette patients, subsequent studies have not confirmed this elevation (50). Interest in possible alterations in relative densities of brain D2 and D1, DA receptors has increased following a report of a relationship between density and tic severity in twins (53).

Autism

A case for altered DA functioning in autism can be made, based on its clear role in mediating motoric disturbances (e.g., stereotypies) and the observation that DA blockers are effective in treating some aspects of autism. The majority of relevant neurochemical studies have examined levels of HVA (32). The concentration of HVA in CSF does not appear to be altered (54). Measurements of HVA in urine have been inconsistent and the only study of plasma HVA reported similar levels in autistic and control subjects (55). Other relevant measures include urinary DA, reportedly normal in autism, and plasma prolactin, which also has been reported to be normal in autistic subjects (55). Taken together, the studies suggest that central dopaminergic functioning, to the extent it can be assessed by the measures employed, is normal in autism.
FIGURE 6.1.1.6. Noradrenergic neurotransmission. Diagrammatic illustration of a noradrenergic neuron. Norepinephrine (NE) synthesized from dopamine by the enzyme dopamine-β-hydroxylase (DBH) can be taken up by the vesicular monoamine transporter (VMAT2) and stored in vesicles for subsequent release or metabolized by the mitochondrial enzyme monoamine oxidase. Released NE can interact with presynaptic or postsynaptic

receptors. Inhibition of the norepinephrine transporter (NET) by NE reuptake blockers results in higher levels of synaptic and extracellular fluid of NE and leads to greater NE receptor stimulation.

NORADRENERGIC SYSTEM

Noradrenergic Neural Transmission/Neuroanatomy

About half of all noradrenergic neurons (i.e., 12,000 on each side of the brain stem) are located in the LC. They provide the extensive noradrenergic innervation of the cortex, hippocampus, thalamus, cerebellum, and spinal cord. The remaining neurons are distributed in the tegmental region. They innervate predominantly the hypothalamus, basal forebrain, and spinal cord. Norepinephrine (NE) is released into the synapse from vesicles; amphetamine facilitates this release (Figure 6.1.1.6). NE acts in the CNS at two different types of noradrenergic receptors, α and β.

Adrenergic α-receptors can be subdivided into α_1-receptors, which are coupled to phospholipase and located postsynaptically, and α_2-receptors, which are coupled to G_i and located primarily presynaptically (Figure 6.1.1.6). Adrenergic β-receptors in the CNS are predominantly of the β_1 subtype. β_1-receptors are coupled to G_s and lead to an increase of cyclic AMP. NE is removed from the synapse by catabolism by COMT and through uptake by the norepinephrine transporter (NET), a Na^+/Cl^--dependent neurotransmitter transporter. Once internalized, NE can be degraded by the intracellular enzyme MAO; metabolic end products include 3-methoxy-4-hydroxyphenylethleneglycol (MHPG) and vanillylmandelic acid (VMA).

Noradrenergic projections modulate sleep cycles, appetite, mood, and cognition by targeting the thalamus, limbic structures, and cortex. Also, the LC receives afferents from the sensory systems that monitor the internal and external environments. The widespread LC efferents lead to an inhibition of spontaneous discharge in the target neurons. Stress responses, central and peripheral arousal, and learning and memory are all critically modulated by noradrenergic neurons (56,57). The critical role of the noradrenergic system in the stress response is shown in Figure 6.1.1.7. The extensive interaction of the central/peripheral NE system with the hypothalamic–pituitary–adrenal (HPA) axis is evident and is summarized in the review of Chrousos and Gold (58).

Noradrenergic Pharmacodynamics

Noradrenergic agents function through a variety of mechanisms. Monoamine oxidase inhibitors (MAOIs) act to increase intra- and extracellular NE by inhibiting

enzymatic catabolism by MAO. A number of antidepressant drugs, including desipramine, nortriptyline, atomoxetine, and venlafaxine, increase extracellular NE via blockade of the NET (Figure 6.1.1.6) (59). Clonidine and guanfacine are potent α_2-receptor agonists and tend to decrease noradrenergic tone by stimulating presynaptic α_2-autoreceptors in the locus coeruleus. This can lead to sedating and hypotensive effects. However, their actions at postsynaptic α_2-receptors in the cortex may be important to their apparent beneficial effects on attention and impulse control (57). The other major class of adrenergic receptors consists of the β_1 and β_2 adrenergic receptors. The β_1 subtype is found in the cerebral cortex, while both types are found in peripheral vasculature. While the more lipophilic β-blockers (e.g., propranolol) can antagonize both central and peripheral β-receptors, peripheral blockade affected by less lipophilic agents (e.g., nadolol) may be sufficient to have behavioral effects.

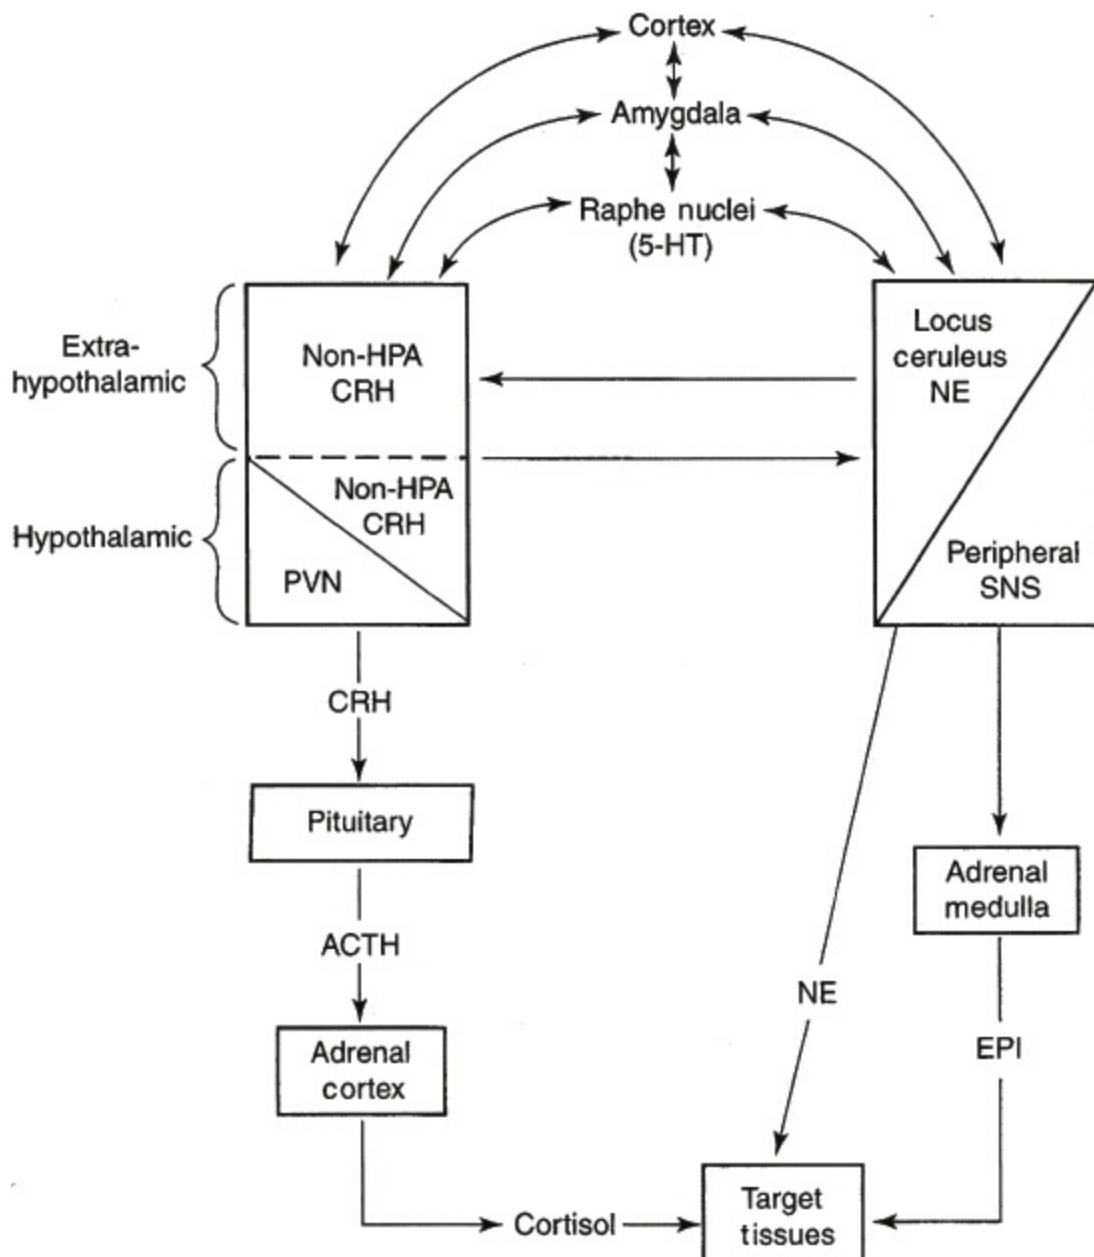

FIGURE 6.1.1.7. Stress response system. Diagram of the two major components of the stress response system: the central noradrenergic/sympathoadrenomedullary system and the hypothalamic–pituitary–adrenal (HPA) axis. The extensive interaction of the central/peripheral norepinephrine systems with the HPA axis is evident. Not shown are the extensive hormonal and neuronal inputs and feedback occurring from the periphery to the central nervous system.

Biologic Psychiatry of Norepinephrine

Given the apparent importance of stress and trauma in affecting the onset, expression, and severity of various forms of psychopathology, it is not surprising that NE has been extensively investigated in biologic psychiatry. Certainly, central NE and the noradrenergic sympathetic nervous system (SNS) play a central role in arousal and the stress response.

Tourette Syndrome

The importance of noradrenergic projections from the LC in controlling states of arousal, as well as reports of symptom amelioration after treatment with the α_2-agonist clonidine (60), are suggestive evidence for altered noradrenergic functioning in TS. There are several reports of lowered urinary excretion of MHPG in TS; however, this finding has not been consistently replicated. Assessment of the SNS by measurement of autonomic cardiovascular measures has not revealed any substantial differences in the TS group (61). However, studies of plasma, urinary, and CSF stress hormones before and after a lumbar puncture clearly suggest that at least some patients with TS have an increased stress response (62,63). This conclusion is consistent with the results of the largest study of NE and MHPG in CSF, which found that, although MHPG levels were normal, concentrations of NE were elevated nearly twofold (38). Given the much shorter half-life of NE compared to MHPG, the results are indicative of normal basal stress response functioning and increased acute stress responsivity.

Attention-Deficit Hyperactivity Disorder

Arousal mechanisms almost certainly play an important part in ADHD-associated symptoms of hyperactivity, impulsivity, distractibility, and inattention (64,65). The crucial role of the central noradrenergic system and SNS in regulating arousal, together with noradrenergic effects of stimulant medication, has led to hypotheses of noradrenergic involvement in ADHD (66,67). Treatment studies employing the noradrenergic-specific agents clonidine and guanfacine, as well as an increasing

appreciation of the role of central NE in attention and cognition (56,57,68), have served to maintain interest in the role of NE in the symptoms of ADHD.

Baseline measurements of NE in serum and MHPG in plasma have not revealed differences between ADHD and control subjects. The data with respect to MHPG and NE in urine are less consistent, with MHPG excretion, for instance, decreased, unchanged, or increased in ADHD (69). Research establishing a positive association between classroom performance and epinephrine (EPI) excretion (70), along with reports of stimulant-induced EPI release and longstanding observations of cognitive enhancing effects of systemically administered EPI, suggest a possible role for EPI in attention. Several reviews have discussed how altered interaction of the adrenergic and noradrenergic systems might contribute to symptoms of ADHD (66,67,71). Although studies of baseline EPI excretion have not found differences between ADHD and control groups, three studies (72–74) have found substantially lower rates of EPI excretion during cognitive testing in ADHD patients compared to normal controls. In studies examining the effects of amphetamine or methylphenidate in patients with ADHD, both drugs increased EPI excretion, but relatively smaller adrenomedullary responses were seen in patients compared to controls following acute (75) or chronic (76) dosing. A similar reduced adrenomedullary response was observed in children with ADHD during hypoglycemic challenge when plasma levels of EPI were measured. Thus, the finding of a blunted EPI response in ADHD has been seen consistently across a number of situations. In the most recent study (72), the blunted response appeared to be specific to the inattention component or domain of ADHD. Further work in this area appears warranted: It would not be surprising if genetically determined variations in the functioning of each of the catecholamines contributed some part to one or more of the component behaviors of ADHD.

Autism

As one of the two major components of the stress response system (58), the sympathetic/adrenomedullary system has been of interest in autism owing to the hyperarousal, hyperactivity, and overreaction to novel situations often seen in autism. It should be mentioned that the HPA axis, the other major component of the stress response (Figure 6.1.1.7), has also been well studied in autism. The functioning of the sympathetic/adrenomedullary system has been assessed through measurements of NE and EPI in plasma or urine. In addition, plasma and urine levels of the major NE metabolites, MHPG, and VMA have been determined. Serum levels of dopamine-β-hydroxylase—the synthetic enzyme secreted along with NE from sympathetic neurons—also have been studied (77). In nearly all cases, indices that reflect basal functioning of the sympathetic/adrenomedullary system were found to be normal in patients with autism. On the other hand, most of the studies measuring indices of acute stress response have found elevations in patients with autism when they are exposed to the stress of a venipuncture or neuropsychological test. Taken together,

the data support the idea that stress response systems are hyperresponsive when individuals with autism are stressed, but that autistic patients are not in a chronic state of hyperarousal. Findings from studies of HPA axis function are consistent with the sympathetic/adrenomedullary results, and support the same conclusions.

The apparent increased response to stressors could result from a difference in the level of perceived stress, an overelicitation of the physiologic response, or an abnormality in the stress response systems themselves. It will be difficult to determine whether the individual with autism experiences a greater threat, if the response to the threat is less well regulated, or both. Despite the difficulties encountered in stress response research in autism, further research in this area is warranted, given the clinical relevance and possible etiologic nature of alterations in this area.

GLUTAMATERGIC SYSTEM

Glutamatergic Neural Transmission/Neuroanatomy

Glutamatergic neurons are widely distributed throughout the brain (see Figure 6.1.1.1). Prominent glutamatergic pathways are the cortico-cortical projections, connections between thalamus and cortex, and projections from cortex to striatum (extrapyramidal pathway) and to brain stem/spinal cord (pyramidal pathway) (78).

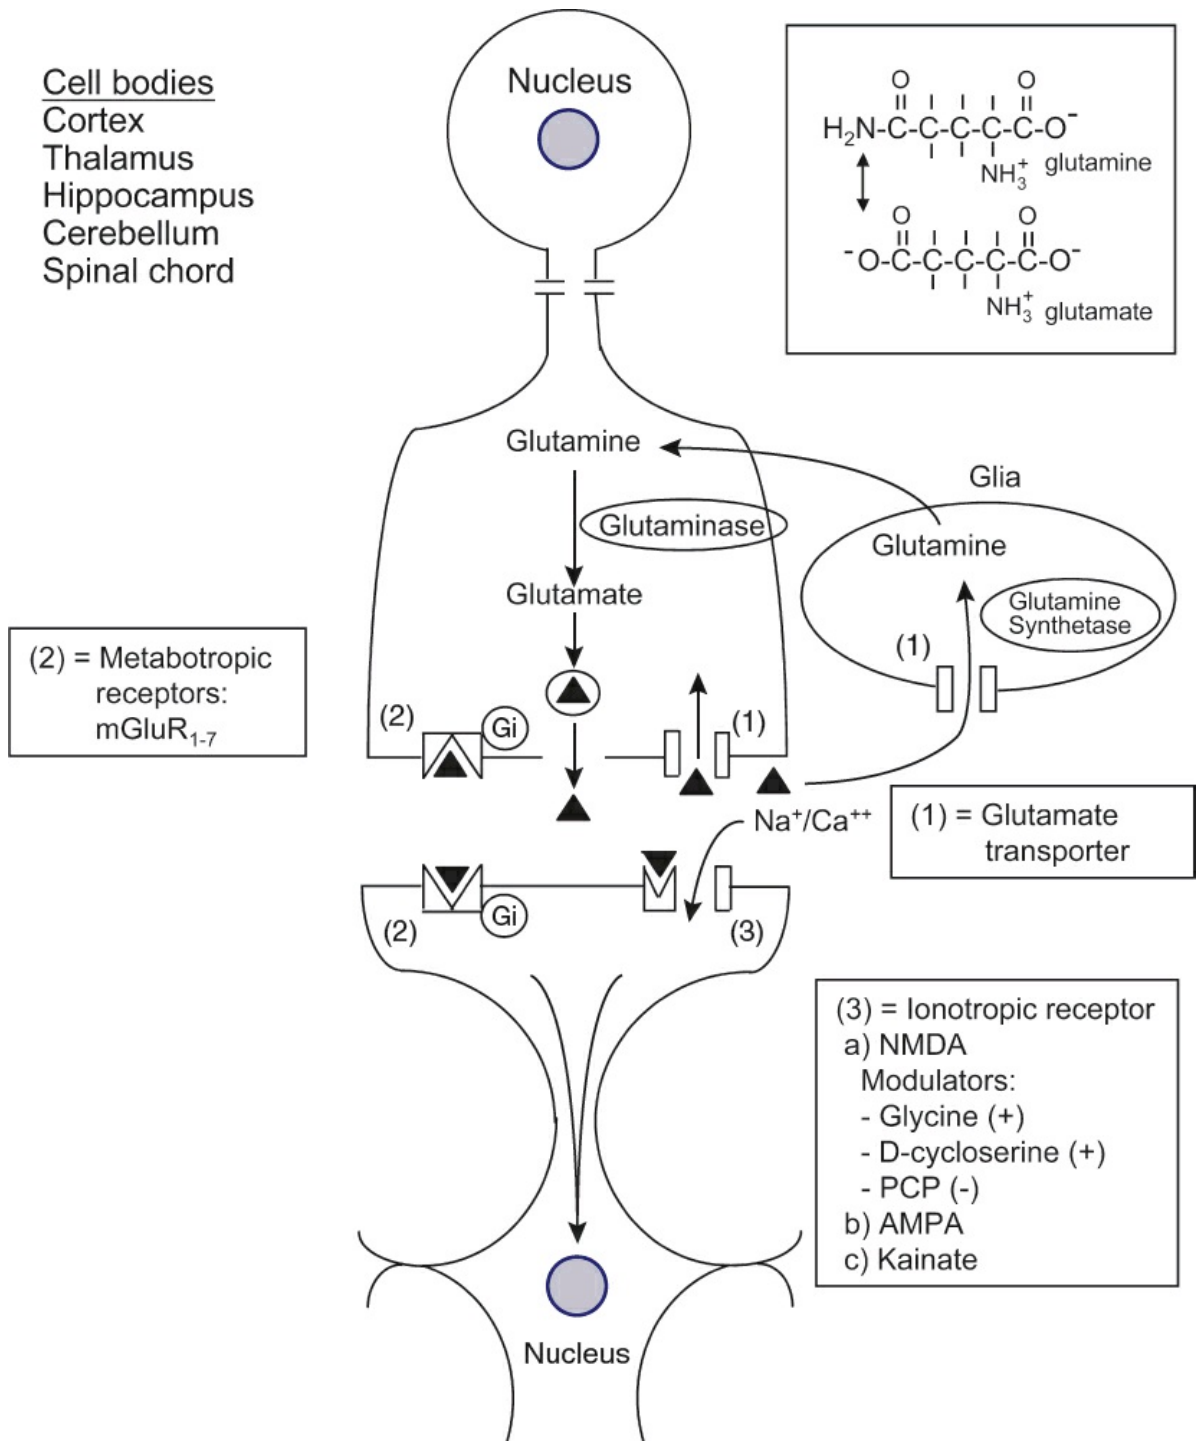
Glutamate acts at three different types of inotropic receptors (Figure 6.1.1.8) and at a family of G-protein–coupled (metabotropic) receptors (79,80). Binding of glutamate to the inotropic receptor opens an ion channel allowing the influx of Na^+ and Ca^{2+} into the cell. NMDA receptors bind glutamate and *N*-methyl-D-aspartate. The receptor is comprised of two different subunits: NMDAR1 (seven variants) and NMDAR2 (four variants). The NMDA receptor is highly regulated at several sites. For example, the receptor is virtually ineffective unless a ligand binds to the glycine site and it is blocked by binding of ligands (e.g., ketamine and phencyclidine [PCP]) to the PCP site inside the channel. AMPA receptors bind glutamate, AMPA, and quisqualic acid, whereas kainate receptors bind glutamate and kainic acid.


FIGURE 6.1.1.8. Glutamatergic neurotransmission. Diagram of the glutamatergic neuron with the pertinent processes of neural transmission and metabolism depicted. Intraneuronal glutamate is taken up into vesicles by the vesicular glutamate transporter. Released glutamate can stimulate pre- and postsynaptic receptors and be taken up by the membrane glutamate transporter (1). The glutamate–glutamine shunt through glial cells is an importance source of releasable glutamate. An **inset** depicts the interconversion of glutamate (glutamic acid) and glutamine.

The metabotropic glutamate receptor family includes at least seven different types

of G-protein–coupled receptors (mGluR1–7). They are linked to different second messenger systems and lead to the increase of intracellular Ca^{2+} or the decrease of cyclic AMP. The increase of intracellular Ca^{2+} leads to the phosphorylation of target proteins in the cell. Glutamate is removed from the synapse by high-affinity reuptake; two transporter proteins are expressed in glial cells and one in neurons (Figure 6.1.1.8). After uptake into glia, glutamate is converted to glutamine by glutamine synthetase. Glutamine can then diffuse back into the neuron to replenish neuronal glutamate after hydrolysis by mitochondrial glutaminase completing this cycle, termed the glutamine–glutamate shunt.

Glutamate has an effect on many brain functions. For example, glutamatergic neurons and NMDA receptors in the hippocampus are important in the creation of long-term potentiation, a crucial component in the formation of memory (81). Excess stimulation of glutamatergic receptors, as seen in seizures or stroke, can lead to unregulated Ca^{2+} influx and neuronal damage (82–84). Decreased glutamatergic function is thought to be involved in the creation of psychotic symptoms.

GLUTAMATERGIC PHARMACODYNAMICS

Glutamate appears ineffective at the NMDA receptor unless glycine or serine is bound at the strychnine-insensitive glycine modulatory site. PCP and ketamine can block the activity of the NMDA receptor by binding to the PCP site within the NMDA-associated ion channel. Ketamine and PCP can induce psychotic symptoms, though ketamine may prove to be useful therapeutically in certain circumstances. Conversely, serine, *d*-cycloserine, glycine, or inhibitors of glycine uptake have been reported to be useful in decreasing psychotic and/or negative symptoms in schizophrenia (85–87); however, more recent trials have not been impressive in this regard (88).

Antagonists at the AMPA receptor are being studied as possible therapeutic agents in infantile seizures, while ampakines or positive modulators of the receptor complex may offer a fruitful approach in schizophrenia. Investigation of various ways to manipulate glutamatergic functioning in schizophrenia will remain an active area of research (89) and advances may have relevance to autism and early-onset psychosis.

Biologic Psychiatry of Glutamate

Schizophrenia

Although a hypoglutamatergic theory of schizophrenia has been widely touted, the theory is based mainly on consideration of the opposing interrelationships between the dopaminergic and glutamatergic systems and on the psychotomimetic effects of

glutamatergic agents, including PCP and ketamine. Postmortem brain research has yet to yield consistent findings with respect to glutamatergic markers in schizophrenia.

Tourette Syndrome

In the one study of central excitatory amino acids in TS, postmortem brain levels of glutamate were lowered in the three projection areas of the subthalamic nucleus (40); it was hypothesized that this might lead to disinhibition of the thalamocortical circuit. This would tend to place TS in the group of hyperkinetic movement disorders, including Huntington's disorder and hemiballismus. As reviewed by Swerdlow and Young (90), further research is needed to clarify basal ganglia functioning in TS. Imaging studies (91) and postmortem research have provided interesting leads to consider with respect to the functioning of cortico-striato-pallido-thalamocortical pathways.

GABAergic SYSTEM

GABAergic Neural Transmission/Neuroanatomy

GABAergic neurons can be divided into two groups (Figure 6.1.1.1): (a) short-ranging neurons (also called interneurons or local circuit neurons) in the cortex, thalamus, striatum, cerebellum, and spinal cord; and (b) medium- and long-ranging neurons in the basal ganglia, septum, and substantia nigra.

GABA acts at two types of receptors, the $GABA_A$ and $GABA_B$ receptors. The $GABA_A$ receptor is a receptor–channel complex comprised of five subunits (92). Activation leads to the opening of the channel, allowing chloride ions to enter the cell, resulting in decreased excitability. Five distinct classes of subunits and multiple variations in the composition of the $GABA_A$ receptor are known. The receptor can be modulated by benzodiazepines (BZs) at the BZ subunit and by barbiturates and ethanol near the chloride channel (Figure 6.1.1.9). The BZ site is further subclassified into α_1, α_2, and α_3 and four types.

The $GABA_B$ receptor is a G-protein–coupled receptor with similarity to the metabotropic glutamate receptor (93,94). The $GABA_B$ receptor is linked to G_i (decreasing cyclic AMP and opening of K+ channels) and G_o (closing Ca^{2+} channels). GABA is removed from the synapse by a sodium-dependent GABA uptake transporter (Figure 6.1.1.9). Cortical and thalamic GABAergic neurons are crucial for the inhibition of excitatory neurons.

GABAergic Pharmacodynamics

Positive modulation of $GABA_A$ receptors is beneficial in the treatment of anxiety disorders, insomnia, and agitation—most likely because of a general inhibition of neuronal activity. The benzodiazepines, including lorazepam, clonazepam, and midazolam, are widely used to treat anxiety despite problems with tolerance and dependence. Somewhat more α_1-specific agents such as zolpidem (Ambien) and related compounds are useful in reducing sleep latency and increasing overall time asleep, and appear to do so without tolerance or rebound effects even after long-term treatment. Furthermore, GABAergic agonists such as benzodiazepines or barbiturates are efficacious in the treatment and prevention of seizures (95). The wide and age-old use of alcohol for self-medication of a number of life's problems is an enduring testament to the importance of the GABAergic system.

GABAergic Biologic Psychiatry

The importance of GABA in basal ganglia neural transmission has led to treatment studies of GABAergic agents (96) in TS. However, studies of CSF GABA have not found group differences in patients with TS and studies of postmortem tissue have not revealed alterations in GABA concentrations. A series of recent studies have indicated that cortical GABA may be reduced in depression and that levels may normalize during treatment with antidepressants (97,98).
FIGURE 6.1.1.9. GABAergic neurotransmission. Diagram of the GABAergic neuron with the pertinent processes of neural transmission and metabolism depicted. Glutamate serves as the major precursor for GABA, with conversion to GABA occurring through the action of glutamic acid decarboxylase (GAD). An **inset** depicts the conversion of glutamate (glutamic acid) to GABA. Released GABA can stimulate pre- and postsynaptic receptors and be taken up by the membrane GABA transporter (2).

CHOLINERGIC SYSTEM

Cholinergic Neural Transmission/Neuroanatomy

Cholinergic neurons in the CNS are either wide-ranging projection neurons or short-ranging interneurons. Projection neurons in the basal forebrain (septum, diagonal band, nucleus basalis of Meynert) project to the entire cortex, hippocampus, and amygdala, and projection neurons located in the brain stem project predominantly to the thalamus. Cholinergic interneurons in the striatum modulate the activity of GABAergic striatal neurons.

Acetylcholine (Ach) acts at two different types of cholinergic receptors. Muscarinic receptors bind ACh as well as other agonists (muscarine, pilocarpine, bethanechol) and antagonists (atropine, scopolamine). There are at least five different types of muscarinic receptors (M1–5). All have slow response times and can be coupled to G-proteins and a variety of second messenger systems. When activated, the final effect can be to open or close channels for K^+, Ca^{2+}, or Cl^- (99).

Nicotinic receptors are less abundant than the muscarinic type in the CNS. They bind ACh as well as agonists such as nicotine (Figure 6.1.1.10) or antagonists such as *d*-tubocurarine. The fast-acting, ionotropic nicotinic receptor allows influx of $Na^+ > K^+ > Ca^{2+}$ into the cell. ACh is removed from the synapse through hydrolysis into acetyl CoA and choline by the enzyme acetylcholinesterase (AChE).

ACh modulates attention, novelty seeking, and memory via the basal forebrain projections to the cortex and limbic structures. Anticholinergic delirium and Alzheimer's disease are examples of a cholinergic-deficit state (100,101). Furthermore, cholinergic interneurons modulate striatal neurons by opposing the effects of dopamine.

Cholinergic Pharmacodynamics

Stimulation of the fast-acting, ionotropic nicotinic receptor with nicotine leads to improvements in attention; however, the addictive properties of nicotine have greatly restricted its use in attentional problems. The acetylcholinesterase inhibitors (AChEIs) are widely used to increase cholinergic function in a more general manner. The AChEIs are most often used to treat the dementia of Alzheimer's; benefits have also been reported in Parkinson and Down syndromes. Like Alzheimer's, the latter disorder appears to have an associated cholinergic deficit. It remains to be seen whether AChEIs like rivastigmine and donepezil will prove of use in treating attention deficits in ADHD and autism.
FIGURE 6.1.1.10. Cholinergic neurotransmission. Diagram of the cholinergic neuron with the pertinent processes of neural transmission and metabolism depicted. Acetylcholine (Ach) is formed by the action of choline acetyltransferase (ChAT), and is metabolized after release by the enzyme acetylcholine esterase (AChE) (3).

Cholinergic Biologic Psychiatry

Autism

Studies of peripheral cholinergic markers in autism are limited. However, several studies have reported decreased nicotinic receptor binding in postmortem brain tissue despite relatively normal levels of the presynaptic markers choline acetyltransferase (ChAT) and AChE, and normal muscarinic receptor binding (102). Thus, epibatidine binding to the a4β_2 nicotinic receptor was reported to be markedly lower throughout the cortex in brain of subjects with autism. Replication of the finding is necessary, but the results to date raise intriguing issues about the possible etiologic role of altered cholinergic functioning during development and the possible therapeutic effects of early manipulation of the cholinergic system.

Attention-Deficit Hyperactivity Disorder

The cholinergic system has been hypothesized to be involved in ADHD, based on its important role in attention and cognition, the high rate of smoking in ADHD (possible self-medication phenomenon), high rates of gestational exposure to maternal smoking, the enhancing effects of nicotine on catecholaminergic systems, and the limited data available on therapeutic effects of nicotinic agents in ADHD. It is not clear whether cholinergic agents, including the AChEIs, will prove to be useful in treating ADHD-related problems.

Tourette Syndrome

The importance of ACh in basal ganglia neural transmission has led to treatment studies using choline and other cholinergic agents (103,104). However, studies of CSF acetylcholinesterase have not found group differences. Though reports of increased red blood cell choline have appeared (105) and muscarinic receptor binding in white blood cells has been reported to be drastically lowered in TS (106), neither observation can be considered definitive.

ACKNOWLEDGMENT

The authors thank Dr. Stephan Heckers of Vanderbilt University for his contributions to an earlier version of this manuscript, and for allowing them to modify and use some of the figures presented.

CHAPTER 6.1.2 ■ CLINICAL AND DEVELOPMENTAL ASPECTS OF PHARMACOKINETICS AND DRUG INTERACTIONS

Jessica R. Oesterheld, Richard I. Shader, and Andrés Martin

OVERVIEW

In the first part of this chapter, the concept of pharmacokinetics is differentiated from pharmacodynamics, and basic clinical pharmacokinetic principles that are shared by children, adolescents, and adults are reviewed, including therapeutic drug monitoring (TDM). Next, the pharmacokinetic differences that distinguish pediatric populations from adults are examined, highlighting the ontogeny of individual cytochromes P450 (CYPs), intestinal and hepatic influx and efflux transporters, and UDP-glucuronosyltransferases (UGTs). Finally, since one of the more clinically relevant applications of pharmacokinetic principles is in helping to understand (and at times to predict) important drug interactions, emphasis has been placed on presenting basic principles that underlie drug interactions and the real-world strategies to prevent them. This chapter serves as a complement to the following and related chapter, in which specific drug classes and individual agents are discussed in detail.

PHARMACOKINETICS AND PHARMACODYNAMICS

Pharmacokinetic principles relate to the handling and disposition of drugs within the body (i.e., those biologic processes that lead to changes over time in drug concentration in body tissues and fluids). In general, drug concentration in a target organ determines how long a drug's therapeutic and adverse effects will last. Changes during development in the processes of drug absorption, distribution, metabolism, and excretion may have an impact on the delivery of drug to target tissues. By contrast, pharmacodynamic principles are concerned with the biochemical and physiologic effects of drugs at their effect sites, with their specific mechanisms of action. Stated succinctly, pharmacokinetics refers to what the body does to a drug and pharmacodynamics to what a drug does to the body (Figure 6.1.2.1). The effects of a medication may change during development, as brain regions or neurotransmitter systems develop and mature at different rates. These developmental changes in neurochemical systems (pharmacodynamic systems) can influence both therapeutic response and side effect profile. For example: (1) Compared to adults, adolescents have a higher risk of dystonic reactions to conventional antipsychotics agents (1,2); (2) prepubertal children appear to be at a higher risk for the activating side effects of the serotonin selective reuptake inhibitors

(SSRIs) (3); and (3) developmental differences in the maturation of noradrenergic pathways may explain, at least in part, why tricyclic antidepressants are less effective in children with depression as compared to adults (4). Taken together, these findings suggest that major neurochemical systems that are altered by psychotropic drug treatments (e.g., dopaminergic, serotonergic, and noradrenergic, respectively) are subject to age-related effects.

BASIC PRINCIPLES

An understanding of pharmacokinetic principles is important for safe and effective patient care. Pharmacokinetic factors are often critical in a variety of clinical decisions, such as choosing between agents within a same drug class, switching between different medication preparations, adjusting dosages, preventing drug interactions, or correctly utilizing and interpreting therapeutic drug levels.

Pharmacokinetics can be conceptualized as having four functionally distinct phases: absorption, distribution, metabolism, and excretion. Absorption and distribution are primarily responsible for determining the speed of onset of drug effect, while the processes of metabolism and excretion terminate the action of the pharmacologic agent by removing the active form of the drug from the body. Taken together, these four phases help to determine the duration of drug activity (5).

Once a drug gains entry to the bloodstream, it is diluted in the plasma and bound at varying degrees to plasma proteins. The drug, usually protein bound, is then either excreted by the kidneys or carried to the liver and transformed to a more water-soluble (and usually inactive) metabolite, which can then be excreted in urine or bile. This complicated and interdependent series of events is designed to reduce the effect of foreign molecules, with the ultimate goal of eliminating the drug from the body (Figure 6.1.2.1). If the dose of a drug is sufficiently large to withstand this "pharmacokinetic assault," then a fraction of a psychoactive drug will cross the blood–brain barrier and endure to produce its pharmacodynamic effect (5). The last step of this process presumes that the drug in question is not a substrate for blood–brain barrier transport proteins that keep certain entities from reaching the brain.

Oral Drug Dose
*Absorption

*Renal clearance
*Blood–brain barrier
Concentration at CNS effect site
Pharmacodynamic response
*Pharmacokinetic Drug Interaction Sites
I/E Trans = Influx/efflux transporters

FIGURE 6.1.2.1. Pharmacokinetics and pharmacodynamics of a CNS drug.

LINEAR AND NONLINEAR PHARMACOKINETICS

A basic working knowledge of key pharmacokinetics principles is relevant to the clinical practice of pediatric psychopharmacology to understand the fate of administered drugs. Some psychotropic medications follow *first-order* (or *linear*) *kinetics,* in which the amount of drug eliminated is proportional to its amount circulating in the bloodstream. Once alterations during absorption have taken place, first-order kinetics provide close to a one-to-one relationship between changes in dosage and in plasma concentration. Such a linear association generally allows for clinically relevant predictions of the impact of a dose change on circulating drug levels (bupropion SR (6), oxcarbazepine (7)). By contrast, *zero-order* (or *nonlinear*) *kinetics* prevail when metabolizing or eliminating mechanisms are exceeded or saturated. This results in a fixed amount of drug being eliminated per unit of time, regardless of the plasma level. Certain drugs (paroxetine (8),

nefazodone (9)) demonstrate zero-order kinetics at clinically relevant doses, making the relationship between dose changes and subsequent plasma levels much less predictable.

Vignette 1

A 12-year-old boy with a diagnosis of obsessive–compulsive disorder is not responding to 10 mg of paroxetine. Would an increase to 20 mg be appropriate? When the dosing of paroxetine is increased from 10 to 20 mg per day in children and teens, the plasma concentration can increase nearly sevenfold instead of a predicted twofold if the drug's kinetics were linear (8). Paroxetine inhibits its own catabolic pathway (CYP 2D6) and interferes with its own elimination. It could be prudent to increase the dose to 12.5 mg per day.

MULTIPLE DOSING TO AVERAGE STEADY-STATE CONCENTRATION

For drugs that follow first-order kinetics, the concepts of elimination half-life and of steady-state concentration are relevant for the practicing clinician. The elimination half-life ($t_{1/2}$) is the time required for the concentration of drug to decrease by one-half. This term is also referred to as the beta-phase half-life or the biologic half-life. We prefer the term elimination half-life since it makes this concept distinct from the half-life of absorption and the half-life of biologic activity. In clinical practice, this parameter is usually assessed by measuring the decay of plasma or serum drug concentration and is referred to as the plasma or serum half-life. Plasma half-life values can be useful when determining dosing intervals. At consistent dosing intervals, it is the plasma half-life that determines the average plasma *steady-state concentration* (C_{SS}). C_{SS} is reached when there is an equilibrium between the amount of drug ingested and the amount of drug eliminated, resulting in no net change in plasma concentration over time, and it is attained after four to five half-lives. The same time is necessary for reaching a new C_{SS} if daily dosing is increased or decreased or for complete elimination after drug intake is abruptly stopped (Figure 6.1.2.2). Most of the drugs commonly used in child psychiatry reach C_{SS}. However, in extensive CYP 2D6 metabolizers, neither psychostimulants nor atomoxetine does because of very short half-lives and therapeutic effectiveness at low concentrations. Carbamazepine, which induces its own metabolism, may take a much greater time to reach C_{SS}.
FIGURE 6.1.2.2. Multiple drug dosing leads to steady-state concentration.

Vignette 2

A 14-year-old girl with major depression has failed a trial of fluoxetine, and she has been treated with 150 mg of twice-daily bupropion SR for 2 weeks. She has developed adverse cognitive effects. The clinician wishes to know if he discontinues the drug, how long before the adverse effects are likely to diminish. The half-life of bupropion SR in youth is approximately 12 hours (6), and in four to five half-lives or 2 to 3 days, it will be eliminated. This is an approximate answer because certain side effects may have a different concentration–response relationship from the main therapeutic effects.

THERAPEUTIC DRUG MONITORING

C_{SS} is sometimes misunderstood by clinicians to imply an absence of daily peak and trough concentrations. Peak and trough concentrations exist within each dosing interval, and when maximum and minimum drug concentrations are the same with two or more successive doses, C_{SS} is reached (Figure 6.1.2.2). Dosing some drugs once a

day because they have a sufficiently long half-life may lead to excessive peak concentrations that can be associated with toxicity or increased adverse effects (e.g., clozapine is dosed twice daily because of potential for seizures at peak concentration). As Figure 6.1.2.3 shows, if the initial dose is doubled and dosed once daily, the peak concentration exceeds the desired concentration to toxicity, but if the original dose is doubled but given twice daily, the concentration is above the plasma concentration that is likely to produce a clinical effect, the minimal effective concentration (MEC), but below toxic levels, the maximal tolerable concentration.
FIGURE 6.1.2.3. Changes in plasma concentration with changes in amount of drug or frequency of dosing.

Clinicians must tailor drug dosing and frequency to maximize the probability of drug efficacy and to minimize toxicity. Some drugs (lithium, valproate, carbamazepine, and nortriptyline) that have narrow therapeutic indices, significant consequences associated with toxicity, wide interpatient variability, and no clinical endpoint to guide drug dosing, are candidates for TDM. A final requirement must be met: The concentration of a drug must have a proportional relation to the concentration and the pharmacologic action at the receptor site (10). Ranges of concentrations have been established for drugs that meet these requirements, and values for psychotropic drugs used by child psychiatrists are given in Chapter 6.1.2.

The range between subtherapeutic and toxic doses, or *therapeutic range*

(sometimes called the therapeutic window) is a misnomer of sorts, since even when drug concentration is within the range, not every youth will respond to the drug, and a percentage will experience toxicity. For some drugs, there are data only on the MEC. TDM can reveal individuals with unusual metabolism (see the Metabolism section), uncover nonadherence, demonstrate increased or decreased concentration with the addition of other drugs (see Drug Interaction section), and confirm toxicity. TDM provides information that supplements clinical assessment.

There are two common errors in using TDM: not waiting for C_{SS} to occur before drawing a blood sample, and not drawing the blood sample at trough level.

As Figure 6.1.2.4 shows, sampling at "trough," or just before the next dose, offers the flattest part of the curve. For drugs given two or three times daily, sampling blood concentration *before the* am *dose in the morning* is recommended, and for drugs given once daily, sampling *before the next dose* is suggested.

Vignette 3

A 17-year-old girl with bipolar disorder has been maintained on 600 mg of lithium carbonate twice daily. A trough level of lithium of 0.8 mEq/L has been maintained for 8 months, with reduction in her symptoms. Parents phone the clinician because their daughter is nauseated and vomiting. As previously instructed, the teen has not been given her morning medication. The finding of a trough level of 1.4 mEq/L initiates careful inquiry and reveals that friends have been giving her ibuprofen for menstrual cramps. By inhibiting prostaglandins, NSAIDs affect renal blood flow and thus the renal clearance of lithium (11).
FIGURE 6.1.2.4. Idealized plasma curve.

There are many pharmacokinetic similarities between adults and children and adolescents. Indeed, age-independent genetic influences on metabolism can be more salient than those influences attributable to age and developmental change. Nonetheless, children and adolescents do display unique pharmacokinetic parameters. Premature infants, neonates, toddlers, children, and adolescents are not a homogenous group in terms of drug distribution patterns (12). These differences can be especially dramatic both at the neonatal stage and around the time of puberty, when the release of gonadal hormones can strongly influence plasma drug concentrations (13).

FACTORS AFFECTING DRUG DISPOSITION

Absorption and Bioavailability

Drugs gain entry into the body through a variety of portals. The *bioavailability* of a medication in the systemic circulation—the amount of unbound drug available to exert a biologic effect on target tissues—is determined by its absorption and, for orally administered medications, by *presystemic clearance (first pass effect)* from intestinal and hepatic transporters, metabolism, and conjugation (see Intestinal Influx and Efflux Transporters and Intestinal Metabolism section) and protein binding. Drugs have variable *first pass effects.* Some drugs are metabolized very efficiently on first pass (60% to 70%) and others less so (less than 30%). Bioavailability measures the completeness of drug absorption, and it is determined in reference to intravenous dosing. Oral administration is by far the most common portal of entry but often the most unpredictable in terms of final bioavailability. Some drugs are given to children as tinctures or in alcohol-based syrups. Although drugs like penicillin G are absorbed in the stomach, most psychotropic medications are absorbed in the proximal small intestine.

Little information is available regarding the effect of age on the absorption of psychotropic medications, although there are several theoretical considerations regarding the influence of this process in children and adolescents. A major factor influencing gastrointestinal absorption is pH-dependent diffusion. In infants, the gastric pH is nearly neutral in the first week after birth. It slowly reaches adult values by age 3 (14). In toddlers, stomach contents tend to be less acidic than in adults, causing weakly acidic drugs to be more highly ionized. Because it is the unionized fraction that is absorbed from the stomach, weakly acidic drugs may be absorbed more slowly in children. This process theoretically could affect phenobarbital and other anticonvulsants, amphetamines, and antidepressants (15).

Other factors that could reduce overall absorption are gastric and intestinal transit time. Gastric transit time is likely increased in neonates and infants, and the age of

maturation is not known (14). Intestinal transit time is increased and the absorptive surface area of the intestine is reduced in young children, suggesting that drugs with a long phase of absorption (e.g., carbamazepine) and some sustained-release preparations may be incompletely absorbed (16). It is important to remember that although the rate at which many drugs are absorbed is slower in neonates and infants, there are no data indicating a generally reduced absorption of orally administered drugs in prepubertal children or teenagers (17).

Intestinal Influx and Efflux Transporters and Intestinal Metabolism

Until 10 to 15 years ago, it was believed that the first pass effect was limited to the hepatic metabolic enzymes and conjugation, and that diffusion was the only mechanism involved in absorption in the small intestine. It was known that lipid-soluble drugs passively diffuse through the apical membrane of the small intestine, that some small hydrophilic ionized drugs squeeze through intracellular junctions, and that both types of drugs cross the cytosol and exit the basolateral membrane into the portal circulation (18). It is now known that non–lipid-soluble drugs are also actively transported (both imported and exported) across these liminal boundaries by members of the solute carrier family of transporter proteins that currently include 43 subfamilies and 298 transporter genes (19,20) (Figure 6.1.2.5). Several names exist for each transporter especially in the earlier literature.

The best characterized of these influx transporters is the peptide transporter 1 (PEPT1). This transporter uses the intestinal–cellular proton gradient as a source of energy to ferry dipeptides and tripeptides across the apical membrane. Hundreds of peptides and other molecules are possible substrates (betalactam antibiotics, ACE inhibitors, thrombin inhibitors, acyclovir, sulpiride, and others). After crossing to the cytosol, these drugs are shepherded across to the portal circulation by a second peptide transporter embedded in the basolateral membrane (Figure 6.1.2.5) (21). Although the development of SLC15A1 has been studied in mice and rats, there is no information about when it matures in humans. Targeting the peptide transport system represents a new strategy for drug delivery of poorly absorbed drugs. Acyclovir, a polar antiviral drug, is poorly absorbed from the intestine, but if the L-valyl ester prodrug valacyclovir is given, it is transported by SLC15A1, and therapeutic levels can be obtained. The ester drugs like methylphenidate are also hydrolyzed by plasma esterases. In the case of methylphenidate, the inactive metabolite ritalinic acid is formed. In the case of acyclovir, an active metabolite is formed.

Efflux transporters are also embedded in both of the intestinal membranes. Members of a superfamily of transporters that use ATP as an energy source (ATP-binding cassette transporters or ABC transporters) (20) can flip compounds which have entered the cytosol back into the intestinal lumen on the apical side and from the

cytosol into the portal system on the basolateral side (Figure 6.1.2.5). Efflux transporters act not only to limit drug absorption and bioavailability in the intestine, but they efflux compounds into the biliary system and the kidney, protect “sanctuaries” such as the brain (Figure 6.1.2.1), and are responsible in part for resistance to cancer drugs.

About 30 years ago, Juliano and Ling (22) noted that after initial efficacy, many oncologic drugs stopped being effective at the same time; they named this phenomenon multiple drug resistance (MDR). A gene on chromosome 7 (MDR1) was found to encode a glycoprotein (P-glycoprotein [P-gp]) that pumps out compounds from cells. Multiple drugs were affected at the same time because all of them were P-gp substrates.

P-gp is now numbered 1 of subfamily B of superfamily ABC (ABCB1). Other members of this family involved in efflux drug transport are in subfamily C (Figure 6.1.2.5). There is an avalanche of in vitro data on what compounds are substrates of these transporters, and how other drugs, foods, or genetic variations can affect ABCB1. Since ABCB1 is saturable in vivo*,* only drugs that are therapeutic in low doses can be shown to be affected (digoxin, talinolol, fexofenadine (23)). Drugs that affect ABCB1 either through inhibition or induction represent a new form of drug interaction. For example, quinidine, an inhibitor of ABCB1, blocks the efflux of digoxin in the kidney, and more digoxin will be absorbed and enter the circulation ((23); see Drug Interaction section).

In the intestine, both ABCB1 and CYP 3A4 are located in the endoplasmic reticulum. There is a considerable overlap in compounds that are substrates of both (dexamethasone, diltiazem, and vincristine).

ABCB1 and CYP 3A4 act together as an intestinal defense tag team to protect against exogenous compounds: ABCB1 provides a barrier to absorption and any remaining compound is converted by CYP 3A4 to less active metabolites ((24); see Metabolism section and Drug Interaction section). Levels of both ABCB1 and CYP 3A4 are higher in the intestine than in the liver, and there is a growing awareness of the importance of these intestinal proteins as compared to hepatic ABCB1/CYP 3A4 in first-pass metabolism. There is no coordination between the duodenal and the hepatic tag teams, and in each organ there is a different ontogeny of CYPs and ABCB1 ((25); see Metabolism section). ABCB1 is also found in the blood–brain barrier, in the prostate, and in the placenta.
FIGURE 6.1.2.5. Intestinal transporters.

Drug Distribution and Plasma Proteins

Following absorption, drugs are distributed into intravascular and various extravascular spaces. Numerous physical factors can influence the distribution of a drug throughout the body: the size of body water compartments and adipose tissue depots, cardiac output, regional blood flow, organ perfusion pressure, permeability of cell membranes, acid–base balance, and binding to plasma and tissue proteins (13). Each of these factors may change during development, resulting in changes in the distribution of a drug and, subsequently, in its pharmacologic effect.

Drugs are transported in the general circulation in two forms that are in dynamic equilibrium with each other: bound to plasma protein (acidic drugs to albumin and basic drugs to alpha 1-acid glycoproteins) and unbound (free). Only the unbound drug is usually available to pass across membranes and to have pharmacologic effects. Although albumin and alpha 1-acid glycoproteins are reduced in the neonate and infant, this does not appear to be an important developmental factor in older children and adolescents (14,17).

Two important factors affecting distribution that change substantially during development are fat stores and the relative proportion of total body water to extracellular water. The relationship between the amount of drug absorbed (D), also referred to as the concentration at time zero, plasma concentration (Cp), and volume of distribution (Vd) can be summarized by the simple equation: $Cp = D/Vd$. Note that the larger the Vd, the smaller the Cp. The proportion of body fat is highest in the first year of life, followed by a steady decrease until an increase occurs prepubertally (12,26). The adipose tissue of infants has a lower ratio of lipid to water (17). The relative volume of extracellular water is high in children and tends to decrease with development. For example, total body water decreases gradually from about 85% of body weight in a small premature infant to about 70% in the full-term newborn to about 60% in the 1-year-old infant, a level that is generally maintained throughout adulthood. Similarly, extracellular water decreases gradually from about 40% to 50% of body weight in the newborn to about 15% to 20% by age 10 to 15 years (27).

Thus, if weight-based drug administration is utilized, infants will tend to have lower drug plasma levels (17). Drugs that are primarily distributed in body water (lithium) can be expected to have a lower plasma concentration in the pediatric population compared with that in adults because the volume of distribution is higher in children and early adolescents.

Another consideration in distribution of drugs in preterm newborns and infants is the relative permeability of the blood–brain barrier when compared with that in children and adults (14). The blood–brain barrier is formed by capillary endothelial cells that have very tight junctions. Paracellular passive diffusion of hydrophilic substances is blocked, and only low–molecular-weight lipophilic agents can cross the blood–brain barrier. The increased permeability of the blood–brain barrier in infants could result in increased bioavailability of drugs within the central nervous system (CNS), as with anticonvulsants (28).

Compounds can also gain entry into the CNS via solute carrier family transporters (blood to brain (29)). Efflux transporters (especially ABCB1 and ABC subfamily C) in astrocytes and brain capillary cells guard entry to the brain by "flipping" out substrates (amitriptyline, quetiapine, and risperidone) (30). Although the ontogeny of ABCB1 is incompletely understood, there is a suggestion that premature infants may have reduced levels (31).

HEPATIC INFLUX AND EFFLUX TRANSPORTERS AND METABOLISM

Influx and Efflux Transporters

After absorption, drugs are carried to the liver via the portal system. Many drugs are able to passively enter hepatocytes, but large or ionized drugs need active transport. They are transported across the membrane by a variety of solute family carriers, and they are exposed to cytosol CYPs and glucuronide conjugates. Bile acids are similarly transported via specialized influx transporters (the sodium/bile acid cotransporter, NTCP, SLC10A1).

Drugs can be effluxed from hepatocytes into the bile canaliculi via ABC transporters (ABCB1 and ABCC2 transporters), while bile salts have their own unique carrier (bile salt export pump, BSEP, ABCB11). Other ABC efflux transporters can pump out drugs back into the venous circulation (32).

Hepatic Metabolism

Most psychotropic drugs are lipid soluble, which is usually a necessary requirement for absorption, distribution, and availability at receptor sites. To be effectively excreted, however, *lipophilic* drugs need to be metabolized to more polar or

hydrophilic forms (having a greater affinity for water). Although some drugs are renally excreted unmetabolized (lithium, gabapentin), most undergo extensive biotransformation in the intestine and the liver (Figure 6.1.2.6) (33).

Phase-1 metabolic reactions, including *hydroxylation, reduction,* and *hydrolysis,* convert drugs to forms more suitable for elimination. Intestinal and hepatic CYPs are the most important enzyme systems responsible for phase-I reactions, and others include plasma esterases that metabolize methylphenidate, flavin-containing monooxygenases, and aldehyde oxidase (Figure 6.1.2.6). The products of phase-I reactions, collectively referred to as *metabolites,* are usually less active and less toxic than their parent compounds. Notable exceptions of clinical significance are desipramine, the demethylated active metabolite of imipramine, and norfluoxetine, the demethylated long-lived active metabolite of fluoxetine. These metabolites have comparable toxicities to their parent compounds and comparable therapeutic activity.

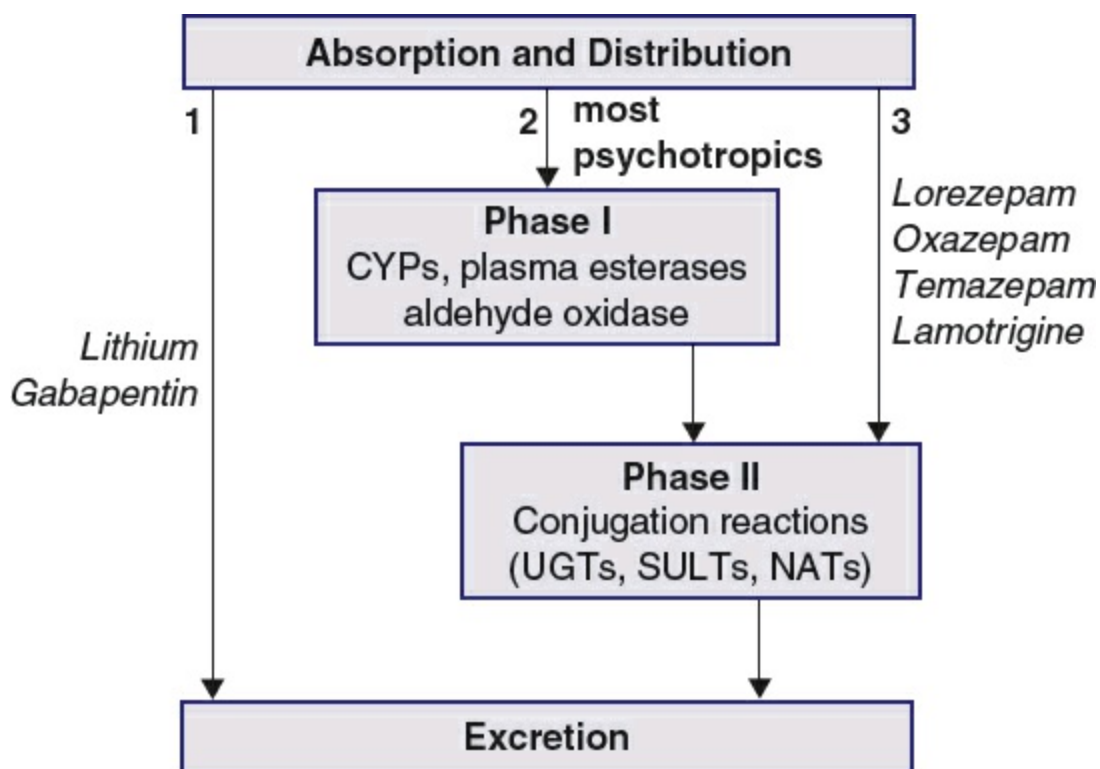
In *phase-II reactions, conjugation* of metabolites generated in phase I takes place with glucuronic acid, sulfate, or others. Conjugated compounds are then readily excreted in urine or other body fluids. It is clinically important to note that some drugs are never metabolized in a phase-I reaction and instead simply undergo conjugation by phase-II enzymes (Figure 6.1.2.6). Drugs such as the 3-hydroxybenzodiazepines (lorazepam, oxazepam, and temazepam) are conjugated by glucuronidation, and they are rapidly cleared at equal rates regardless of age as long as renal function is normal (34). These drugs are preferred in instances of liver insufficiency because other benzodiazepines depend on cytochromes for metabolism, which may be more influenced by hepatic dysfunction than is glucuronidation.


FIGURE 6.1.2.6. Phase I and II.

Cytochromes (CYPs)

CYPs are heme-containing enzymes, located principally in the intestine and liver that metabolize two types of substrates: endogenous (the body's own steroids, lipids, and fatty acids) and exogenous (toxins, drugs). CYPs that metabolize exogenous compounds are located in the endoplasmic reticulum. The sequencing of CYP amino acids has led to a classification system based on similarity (35): Arabic numbers 1 to 4 designate family members, letters A to E label subfamily members, and Arabic numbers note specific enzymes (isoform, gene). CYP 3A4, for example, is a member of family 3, subfamily A, and enzyme 4. The CYPs that are near each other on the same gene and are related are grouped together (CYP 3A4, CYP 3A5, and CYP 3A7) and referred collectively as CYP 3A. It is the major CYP family involved in human hepatic drug metabolism, handling about half of psychotropic drugs. CYP 3A constitutes 30% of total CYP hepatic content and 70% of intestinal CYP content, and it serves as a high-capacity reservoir. The other clinically relevant CYPs include 1A2, 2B6, 2C9, 2C19, 2D6, and 2E1.

Most psychotropic drugs undergo both phase-I and phase-II reactions (Figure 6.1.2.6). A few drugs are metabolized by only one CYP (desipramine via CYP 2D6, triazolam via CYP 3A). Some others undergo phase-II conjugation only (lorazepam, oxazepam, and lamotrigine are glucuronidated only). However, most drugs require multiple CYPs to be completely metabolized. As examples, sertraline is N-demethylated via six different pathways (36), and clomipramine (CMI) demethylated by CYP 1A2, CYP 2C19, and CYP 3A to desmethylclomipramine (DCMI), an active metabolite that is then hydroxylated by CYP 2D6. In addition, CMI is directly hydroxylated by CYP 2D6.

CYP-based metabolism of drugs is influenced by genetic factors. Seven percent to 10% of Caucasians have a genetic deficiency of CYP 2D6 and are thus less efficient at metabolizing CYP 2D6 substrates, including many psychotropic agents. For these "slow metabolizers," blood levels of drugs metabolized by 2D6 may increase considerably as unmetabolized drug enters the blood. Some Asian individuals have a 2D6 variant that causes them to be "somewhat slow" metabolizers, and they require lower dosing of relevant drugs to achieve therapeutic blood levels. Some African Americans also have an allelic variant of CYP 2D6 that is linked to slow or poor metabolism of CYP 2D6 substrates. CYP 2C9 and CYP 2C19 are also genetically polymorphic. One percent to 3% of Caucasians are slow metabolizers of CYP 2C9, and 18% to 23% of Japanese and 2% to 3% of Caucasians and African Americans are slow metabolizers of CYP 2C19 (37). Fewer than five Caucasians in 1,000 are slow metabolizers of both CYP 2D6 and CYP 2C19, putting them at particular risk for high levels of substrates that are metabolized by *both* pathways (certain

tricyclics, propranolol, and citalopram).

It has been possible to ascertain the CYP genetic status of individuals for some time, but in the last year, the FDA has approved a diagnostic DNA chip for CYP 2D6 (27 variants) and CYP 2C19 (two variants) (38). Clinicians can consider testing youth who have adverse effects with substrate CYP 2C19 or CYP 2D6 drugs at usual therapeutic doses (poor metabolizers or intermediate metabolizers) or who have poor responses with substrate CYP 2D6 drugs at usual therapeutic doses (ultrarapid metabolizer) (39).

UDP-Glucuronosyltransferases

Located close to the CYPs in the endoplasmic reticulum, UGTs are a superfamily of membrane-based enzymes that catalyze the transfer of glucuronic acid to endogenous or exogenous compounds. They are considered to be the principal phase-II system by virtue of the number of different types of compounds they conjugate, as well as their superior quantity compared to other phase-II enzymes. The nomenclature of UGTs is similar to CYPs, being designated by family, subfamily, and gene (UGT 1A1, UGT 2B7).

There are two families of UGTs, UGT 1 and UGT 2, and three subfamilies (UGT 1A, UGT 2A, and UGT 2B). The subfamily of UGT 1A shares exons two to five in common, and they are distinguished by a unique exon one. UGT 1A1 is the most abundant UGT 1 in the liver (40). UGT 2A and UGT 2B are encoded by separated genes. Like CYPs, individual UGTs have both unique and overlapping substrates (Table 6.1.2.1), and they have tissue-specific patterns of expression and genetic variations.

Unlike CYPs, UGTs handle both endogenous and exogenous compounds. Thus, deficient glucuronidation as a result of genetic polymorphism or UGT inhibition can lead to increased levels of both endogenous and exogenous substrates. For example, UGT 1A1 is the only conjugative pathway for bilirubin. Gilbert syndrome (in which UGT 1A1 activity is reduced by about 70%) is characterized by a benign fluctuating bilirubinemia in association with illness or stress. Individuals with Gilbert syndrome can also develop toxic levels of SN-38, the active metabolite of the cancer chemotherapy agent, irinotecan, because UGT 1A1 is an important conjugative pathway for SN-38. The influence of polymorphisms of individual UGTs has been shown to correlate with clinical outcomes of psychotropic drugs such as clozapine, imipramine, and cyproheptadine (UGT 1A4, 41), with levels of the active enantiomer of oxazepam (UGT 2B15, 42), and with intolerance to morphine (UGT 2B7, 43). A new rapid genetic test for UGT 1A1 has been approved by the FDA (44).

The clinical application of knowledge about UGTs has lagged at least a decade behind CYPs, but it may become increasingly clinically relevant. At present, clinicians must understand UGT-based drug interactions to appropriately use

lamotrigine, olanzapine, and others (see Drug Interaction section).

Ontogeny of Hepatic CYPs and Phase-II Enzymes

In the neonate, activities of hepatic CYP-mediated metabolism and the phase-II reactions, UGTs, glutathione conjugation (GST), and acetylation (NAT) are decreased, but some types of sulfate conjugation function efficiently. Since sulfation is a major conjugative pathway of acetaminophen, individuals have speculated that this is the reason why young children are more resistant to the toxic effects of this drug (45).

Neither CYPs nor phase-II enzymes come "on line" at the same time, and each has a unique ontogeny. CYP 3A7 is the predominant fetal CYP. In the first few weeks after birth, CYP 3A4 gradually appears and increases as CYP 3A7 peaks at 2 weeks and fades (46). CYP 3A5 is variably present in some individuals, and it appears to be under genetic control. CYP 2D6, CYP 2C9, and CYP 2C19 become active in the first weeks of life. CYP 2E1 gradually develops over the first 3 months (47). CYP 1A2 is the last CYP to appear at the fourth or fifth month (48). Clinicians must take account of these changes in dosing premature infants and neonates. For example, clinicians must decrease the dosing of midazolam, a CYP 3A4 and CYP 3A5 substrate, as infants are increasing their ability to metabolize it (49).

TABLE 6.1.2.1

UGT TABLE

	UGT1A1	UGT1A3	UGT1A4	UGT1A6	UGT1A
Chromosome	2	2	2	2	2
Genetic variation	Yes	Yes	Yes	Yes	Yes
Some endogenous substrates	Bilirubin Estriol	Estrones	Androsterone Progestins	Serotonin	Thyroxi
Some substrate drugs	Acetaminophen Buprenorphine Ethinyl Estradiol Ibuprofen Irinotecan Mb-SN-38 Nicotine Phenytoin	Buprenorphine (chlorpromazine) (clozapine) Cyproheptadine Diphenhydramine Doxepin (ibuprofen) (valproate)	(amitriptyline) Chlorpromazine Clomipramine Clozapine Diphenhydramine Cyproheptadine Doxepin Imipramine Lamotrigine Loxapine Olanzapine Phenytoin Trifluoperazine	Acetaminophen Phenytoin Valproate	Acetam Ethinyl estradi Ibuprofe Phenyt Valproa

Possible inhibitors	Ketoconazole Probenecid	Imipramine Probenecid	Phenytoin Rifampin Probenecid	Probenecid	Proben Ketoco Valproa

(), minor pathway.

Each CYP has a unique development. CYP 2C19 levels are highly variable from 5 months to 10 years, and levels approach adult values by 10 years of age (50). CYP 2D6 matures to adult levels by 10 years or earlier (46). There is some evidence that levels of CYP 3A4 are actually lower in youth aged 5 to 15 years than in adults (51). CYP 2C9 gradually increases over the first 5 months (and as many as half of individuals may reach adult values), exceeds adult activity in youth from 3 to 10 years, and achieves adult activity after puberty (50). CYP 1A2 activity in childhood exceeds adult levels until after puberty (girls, Tanner stage 2; boys, Tanner stage 4) (52).

There is less known about the development of hepatic phase-II enzymes. The bilirubinemia of premature infants occurs because of the immaturity of hepatic UGT 1A1. Low levels of neonatal UGT 2B7 are responsible for the toxicity of chloramphenicol, the so-called *gray baby syndrome.* Both of these UGTs reach adult values by 3 to 6 months (53), but in some individuals, full maturation may not be reached until 30 months (46). Two UGTs start to develop only after the second year of life: UGT 1A9 and UGT 2B4 (54). It has been speculated that the immaturity of UGTs in young children is partially responsible for their increased risk of valproate hepatotoxicity, and they may produce higher concentrations of a hepatotoxic metabolite of valproate, 4-ene valproic acid (45). Individual enzymes of other phase-II proteins (sulfotransferases [SULTs], N-acetyl transferases [NATs]) have unique stagger-step developments, but most achieve adult levels by 2 to 4 years of age (46).

Plasma Clearances of Liver-Metabolized Drugs by Prepubertal Children

Children under 10 years require larger, weight-adjusted doses of most hepatically metabolized medications than do adults in order to achieve comparable blood levels and therapeutic effects (12,17). The reason for this is not obvious. Originally, it was proposed that the greater liver-to-body mass ratio of children compared to adults and other developmental changes in youth were responsible. However, it has been subsequently shown even when liver volume is normalized, that systemic clearance of a nonspecific CYP substrate (antipyrine) is higher in children when compared to adults (55). It also had been speculated that children have more efficient

CYPs, but when individual hepatic CYPs were evaluated in vitro, no differences in maximal activities were found in children when compared to adults (56). Finally, as outlined above, during development, CYPs and phase-II conjugates have *not* been shown to be uniformly increased in prepubertal children.

Renal Excretion

The kidney is an important organ for drug excretion. Three mechanisms are involved in the renal excretion of drugs: glomerular filtration through which drugs not bound to plasma proteins are "filtered," active tubular secretion in the proximal convoluted tubule, and passive reabsorption from the tubule.

Adult values of glomerular filtration are reached by 3 months in full-term infants, and if weight adjusted, they can exceed adult values thereafter (14). Although in infants, tubular secretion is believed to develop more slowly than glomerular filtration, the efficacy of both mechanisms may be greater in children and teens than in adults (14). There is less information available about the ontogeny of tubular reabsorption, but it may not mature fully until adolescence (14).

Increased glomerular filtration and changes in tubular reabsorption, as well as increased body water in children, are responsible for the fact that children from 9 to 12 years can have greater clearance and shorter elimination half-life of lithium (57). Newer anticonvulsants that are primarily or entirely handled by the kidney (gabapentin, levetiracetam, and topiramate) may also require higher weight-adjusted dosing in prepubertal children (58–60).

DRUG INTERACTIONS: FOCUS ON CYPs

Given the increasing recourse to medication combinations, augmentation strategies, and polypharmacy as an accepted and thoughtful (61) or sometimes as a controversial and potentially problematic (62) practice in child psychiatry, astute clinicians need to be aware and clinically suspicious of potential drug interactions. For children concurrently treated with nonpsychiatric drugs (including seemingly innocuous over-the-counter agents), the degree of oversight needs to be particularly heightened.

Time Courses of CYP-Based Drug Interactions

Drugs that interact with CYPs can inhibit, induce, or have no effect on CYP activity. Drugs with a *low presystemic clearance* (little of the drug is metabolized and conjugated in *the first pass* through the intestine and liver) are more susceptible to CYP induction or inhibition because they have *more unused metabolic capacity.* If a CYP is inhibited, more unmetabolized drug will enter the circulation, leading to increased levels of the drug (similar to a phenotypic slow metabolizer). Since

inhibition requires blocking *existing* pathways, inhibition occurs rapidly for drugs that have a *high presystemic clearance.* The time course of the occurrence of the drug interaction is not changed if a *victim* drug is added to a *perpetrator* inhibitor drug or if a *perpetrator* inhibitor drug is added to a *victim* drug (see Figure 6.1.2.7). When a *perpetrator* inhibitor drug is added to a victim drug, the time to achieve a new C_{SS} is longer than the initial C_{SS} because the half-life has been prolonged, and the full effect of the interaction may not be evident until the *perpetrator* inhibitor reaches C_{SS}. Further, as illustrated by Figure 6.1.2.7, if the *perpetrator* drug is discontinued, the drug interaction will resolve as the concentration of the *perpetrator* drug falls to zero.
FIGURE 6.1.2.7. A, B: Pharmacokinetics of substrate to inhibitor and inhibitor to substrate.
FIGURE 6.1.2.8. A, B: Pharmacokinetics of substrate to inducer and inducer to substrate.

By contrast, if a drug has a *low presystemic clearance,* then the drug interaction will be evident only after both drugs have had several passes through the circulation and the *victim* drug reaches C_{SS}. Therefore the drug interaction will be clinically evident after some time.

Vignette 4

An 18-year-old woman has generalized anxiety disorder for which she has been prescribed daily triazolam for the past year. She develops a significant bacterial

infection and clarithromycin is added. The next day, she develops signs of benzodiazepine toxicity. Triazolam is discontinued, and after 5 days, alprazolam is substituted. The toxicity reemerges 5 days later (63). In this vignette, triazolam has a high presystemic clearance and alprazolam has a low presystemic clearance (even though both are CYP 3A substrates).

If a CYP is induced, additional enzyme will be available for metabolism (similar to a phenotypic ultrarapid metabolizer), leading to lower drug levels. Induction takes some time to start (3 to 10 days) or stop (5 to 12 days), as protein synthesis must first occur and then cease.

The time course of the occurrence of the drug interaction is different if a *victim* drug is added to an already present *perpetrator inducer* drug than if *the perpetrator inducer* drug is added to an already present victim drug. In the first example, the drug interaction will take place quickly because the CYPs are already induced, but in the second, it will occur only after new or additional protein synthesis is initiated. In either case, however, if the perpetrator inducer is discontinued, it will take time for protein synthesis to cease and for the concentration of the perpetrator inducer to decrease. The drug interaction will persist over several days despite the absence of the perpetrator inducer. If both drugs are discontinued at the same time, the half-life of the victim drug will determine the persistence of the drug interaction only if it is less than the time necessary for protein synthesis to cease (see Figure 6.1.2.8).

UGT and Transporter Drug Interactions

Although there are significantly less data, UGTs are also susceptible to inhibition and induction (Table 6.1.2.1). For example, lamotrigine is handled only by glucuronidation (probably UGT 1A4 and UGT 2B7), and the addition of valproate (a UGT 2B7 inhibitor) can significantly elevate lamotrigine levels, and increase the likelihood of the development of life-threatening Stevens–Johnson syndrome (64). The prescribing information of lamotrigine details dosage recommendation for this combination and for other anticonvulsants that induce or inhibit UGTs (65). It is less well known that when coadministered with lamotrigine, ethinyl estradiol (present in oral contraceptives), an inducer of glucuronidation, can reduce levels of lamotrigine up to 50% (66). There are only a few drug interactions involving transporters that are unquestionably tied to a specific transporter and are clinically significant because it is difficult to clearly separate out the effects of transporters from phase-I and phase-II effects and because a drug can have multiple transporters. The best known drug interactions involving efflux transporters are those of digoxin: For example, quinidine inhibits the ABCB1 uptake of digoxin in the kidney, leading to increase in digoxin levels (67). Although the current information about these drug interactions is still meager, as information grows, clinicians will need to keep abreast.

Vignette 5

A 14-year-old girl has diagnoses of major depressive disorder and attention-deficit hyperactivity disorder (ADHD). The depressive symptoms have responded well to fluoxetine at 10 mg per day, but difficulties with attention and impulsivity continue. Because she has had failed trials of methylphenidate and dextroamphetamine, she is begun on nortriptyline. Unaware of a possible drug interaction, the clinician begins treatment with a low dose of nortriptyline and plans to gradually increase dosing. The clinician is surprised to find that after 5 days of 10 mg twice daily of nortriptyline a trough blood level is 85 ng/mL. Fluoxetine is a potent CYP 2D6 inhibitor, and the level of victim CYP 2D6 substrate nortriptyline is already within therapeutic range.

Vignette 6

A 17-year-old youth with a diagnosis of bipolar 1 disorder has failed lithium, valproate, and several atypical antipsychotics. Her manic symptoms are well controlled on carbamazepine. She is sexually active and has been on low-dose oral contraceptives for 1 year without any side effects. The clinician is unaware that carbamazepine is an inducer of CYP 3A4. The patient begins to experience breakthrough bleeding for the first time.

The six most relevant CYPs and selected common psychotropic and other pediatric drugs and herbs metabolized by them are shown in Table 6.1.2.2. Common potent inhibitors and inducers of CYPs are grouped alphabetically by CYP.

The table can be used to anticipate CYP-based drug interactions and to prevent some of the unexpected outcomes depicted in the previous vignettes. If one drug is an inducer or inhibitor and it is listed on the same vertical axis as a substrate (the same CYP), a drug interaction is possible. However, *possible* is not the same as *likely* or *clinically significant.* A drug interaction is more likely to be clinically evident when a new drug is added or an existing drug is discontinued. Three other drug characteristics should help raise a clinician's drug interaction antennae. A drug interaction is especially likely to occur and can be significant if the victim drug has *one major* metabolic pathway (nortriptyline, desipramine, and ethinyl estradiol). Many of the most serious drug interactions occur when a CYP inhibitor or inducer is added to a substrate with a narrow therapeutic index, as exemplified in Vignette 5. Finally, clinicians should be alert if a *perpetrator* inhibitor or inducer is *potent,* as shown in Vignette 6. Potent inhibitors and inducers are marked in bold in Table 6.1.2.2.

Although clinicians can glean important information from this table and from UGT Table 6.1.2.1 to predict drug interactions, they must utilize additional resources.

They should know the metabolic characteristics and common drug interactions of medications they frequently prescribe. Clinicians can research these and other coprescribed over-the-counter and recreational drugs and herbs by using any common search engine on their computer to locate a drug's product insert and to review the "Metabolism" and "Drug Interaction" sections. Alternatively, clinicians can use PubMed to find the metabolic characteristics of a drug by entering the drug name and metabolism. They also can uncover clinical studies or case reports of known drug interactions involving pertinent drugs by entering the names of the drugs and the term drug interaction.

Clinicians need to amass trusted references: books such as Ciraulo's *Drug Interactions in Psychiatry* (68), Cozza's *Drug Interaction: Principles for Medical Practice* (69), articles such as Sandson's *An Overview of Psychotropic Drug-Drug Interactions* (70), websites such as Flockhart's CYP table (71), or Oesterheld's P-glycoprotein, ABCB1 table (72), and UGT table (73). A collegial relationship with a clinical pharmacologist, especially one who is hospital based, should be treasured, since they have access to pharmaceutical references not readily available to clinicians. A patient's primary medical provider and his/her family should be educated to the common drug interactions with prescribed psychotropics and encouraged to be vigilant for their possibility. Drug interaction computer programs can be useful, but they are rarely complete (lacking influx and efflux transporters and phase-II proteins) or up to date. Barron's *Evaluation of Personal Digital Assistant Software for Drug Interactions* (74) places iFacts and Lexi-Interact as the best, and ePocrates Rx as the worst. Although computer programs cannot factor in patient's characteristics such as genetic CYP status or developmental age, some are invaluable because they can sum the effects of multiple drugs if patients are taking many drugs or herbs at the same time (e.g., GenemedRx, 75).

(), minor pathways or modest inhibitor or modest inducer; bold, potent inhibitors.

In evaluating *suspected* drug interactions that may have already occurred, clinicians can use these resources to determine the metabolic characteristic of the involved drugs. They also should determine the time course between the initiation of the drugs and the development of adverse effects to help evaluate the likelihood of the suspected interaction. Does it fit the time courses that have been previously described? Does it fit the immediate development of adverse effects, as exemplified by the addition of a perpetrator inhibitor added to triazolam in Vignette 4, or the delayed timeline of a perpetrator inducer drug added to an oral contraceptive, as in Vignette 6?

CONCLUSION

Understanding the pharmacokinetic and drug interaction principles discussed in this chapter can be useful in clinical practice. It is hoped that readers will find the information in this chapter useful in improving the quality of care of their patients.

CHAPTER 6.1.3 ■ GENERAL PRINCIPLES AND CLINICAL PRACTICE

ANDRÉS MARTIN, JESSICA R. OESTERHELD, MICHAEL H. BLOCH, CHAD BEYER, AND LAWRENCE SCAHILL

INTRODUCTION

The now famous clinical trial conducted by Charles Bradley (1) is often cited as the beginning of pediatric psychopharmacology. In that study, the racemic mixture of levo- and dextroamphetamine (benzedrine) was administered openly to a group of 30 children with mixed behavioral and emotional symptoms. Bradley observed that the children characterized as "noisy, aggressive and domineering" were calmer and more manageable. In the same issue of the *American Journal of Psychiatry,* Molitch and Eccles (2) reported what may be the first placebo-controlled study in child psychiatry. Ninety-three boys described as juvenile delinquents were randomly assigned to gradually escalating doses of benzedrine or placebo. The benzedrine group showed dose-related improvements across a range of measures on learning, motor control, and short-term memory that exceeded the improvements in the placebo group. Since this pioneering work, the field of pediatric psychopharmacology has made steady progress.

Despite clear progress in some areas, there are important gaps between research and clinical practice. For example: (1) there have been over 100 placebo-controlled studies on the efficacy of methylphenidate in the treatment of attention-deficit hyperactivity disorder (ADHD), yet only a few studies have evaluated its long-term effects (3,4); (2) for serious psychiatric disorders such as autism, empirical support for the use of medication remains meager, leaving clinicians and families with limited guidance on appropriate treatment of affected children; (3) despite the demonstrated efficacy and safety of selective serotonin reuptake inhibitors (SSRIs) in the treatment of children and adolescents with obsessive–compulsive disorder (OCD), little is known about the appropriate duration of treatment; (4) while, the empirical foundations for pediatric psychopharmacology are not yet fully anchored, prescribing of psychotropic medications to pediatric population has increased dramatically over the last two decades. Data from the National Ambulatory Care Survey show that in adolescents between 14 and 18 years, the percent of visits to a doctor's office that resulted in a psychopharmacologic prescription rose from 3.4% in 1994–1995 to 8.3% in 2000–2001 (5). Additionally, in 2003–2004 approximately 2 million or 1% of all office visits by children and adolescents involved prescriptions for an antipsychotic (6). Over the past decade, however, there have been several initiatives that are having a substantial impact on the pace of progress in the field.

The purpose of this chapter is to present general principles of clinical psychopharmacology in pediatric populations. Following the discussion of seven overarching principles, this chapter reviews the major classes of psychotropic medications and current approaches to their use in children and adolescents. Drugs within the major classes are considered in terms of their pharmacology, adverse effects, clinical applications and management, and available empirical support. Pharmacokinetic aspects, including drug interactions, as well as mechanisms of action and other pharmacodynamic issues, will be considered only briefly here. Throughout this chapter, the reader is referred to the interspersed tables, in which the most salient information for each drug class and its specific agents are summarized.

Seven Guiding Principles

1. *The Role of Development*. There is a general recognition that development can have a major impact on pharmacologic effects (7). Thus, children and adults may show divergent responses to psychotropic drugs. The sources of these differences, as elaborated in the preceding chapter, are manifold. First, children often metabolize and eliminate drugs from the body more quickly than adults, resulting in shorter drug half-lives. This is apparently due to a larger liver-to-total body ratio and more efficient glomerular filtration rate in children as compared to adults. One practical implication of these pharmacokinetic differences is that in order to achieve therapeutic serum levels for some drugs when compared to adults, children may require higher weight-adjusted (mg/kg) dosages. In addition to pharmacokinetic considerations, because the central nervous system undergoes substantial developmental change during childhood, there can be age effects on drug action as well. For example, activating side effects of SSRIs and other antidepressants (8), and developmental differences in the maturation of noradrenergic pathways may explain, at least in part, why tricyclic antidepressants are less effective in children with depression as compared to adults (9). Taken together, these findings suggest that the three major neurochemical systems that are manipulated by psychotropic drug treatments (dopaminergic, serotonergic, and noradrenergic, respectively) are subject to age effects.

   In recognition of these developmental influences, federal policy initiatives have been instituted to promote studies specific to pediatric populations. First, in 1997 Congress passed the Food and Drug Administration Modernization Act (FDAMA), which offers pharmaceutical companies an additional 6 months of market exclusivity for products that are evaluated in children. For some drugs, this 6-month extension represents a powerful financial incentive. A second policy initiated by the Food and Drug Administration (FDA) requires pharmaceutical companies to evaluate new products in children if they are likely to be used in this population when released into the marketplace (10). A

third and related development was the previous commitment of federal funds by the National Institutes of Health to establish research networks capable of conducting large-scale, multisite studies in pediatric populations (3,11–13). The combined impact of these initiatives has led to rapid growth in the knowledge base of pediatric psychopharmacology and its incorporation into clinical practice.

2. *The Limits of Categorical Diagnoses and Occurrence of Multiple Disorders as the Norm*. The second principle acknowledges the limitations of psychiatric diagnoses and of the current nosologic system of classification. Most psychiatric disorders in childhood are probably heterogeneous with respect to etiology. This presumption is supported by the high cooccurrence of psychiatric disorders in children—both in clinical (14) and in community samples (15). The extent to which these mixed syndromes represent a variant of a given disorder is often unclear, but may be relevant to drug response; for example, tics are a common cooccurring feature in OCD. The presence of tics may signal a different form of OCD and may be associated with a lower probability of positive response to monotherapy with an SSRI in OCD (16,17), and improved response to antipsychotic augmentation (18). Along the same lines, hyperactivity and impulsiveness are common complaints for children with pervasive developmental disorders (PDDs). Results from a multisite study in children with PDDs accompanied by hyperactivity, impulsiveness, and distractibility showed a lower rate of positive response to stimulants compared to what is observed in typically developing children with ADHD. In addition, children with PDDs appear to be at higher risk for adverse events with stimulant treatment (19). Thus, etiologic heterogeneity may explain differences in clinical response. These issues underscore the importance of large treatment studies to identify clinically meaningful subgroups and predictors of positive and negative response.
3. *Target Symptoms and the Integration of Data from Multiple Informants* . This principle concerns the importance of pretreatment assessment and the identification of target symptoms. Given the common occurrence of multiple psychiatric disorders in children, the identification of target symptoms for pharmacologic intervention may be easier said than done. One of the practical challenges in child psychiatry is the requirement of gathering information from multiple sources, including the child and parents at a minimum, and in many cases, the child's teacher, or another caregiver as well. Obtaining data from multiple sources can be aided by the use of behavioral checklists, child self-reports, and clinician ratings. Behavioral checklists completed by parents and teachers permit comparison of the current patient to a normative sample. Clinician-rated instruments can assist with establishing a pretreatment baseline of symptom severity. Some checklists and clinician-rated instruments can also be used to measure change over time. Although checklists and rating instruments can be extremely useful in the evaluation phase and to measure change over

time, they cannot replace the clinical interview and direct observation of parent and child. A closely related challenge is the integration of all available information, in order to identify the most pressing target symptoms and select the most appropriate medication in combination with other needed interventions. The joint agreement on relevant target symptoms by caregivers and clinicians can be useful in monitoring therapeutic outcomes, but may also lead to greater consumer satisfaction with treatment (20).

4. *Adverse Effects: Monitoring Risks and Benefits*. The dramatic increase in the availability of new psychotropic drugs, their expanded use in pediatric populations, and their uncertain impact on development underscore the importance of ongoing assessment of adverse effects. At present, there is no clear consensus on the best method of eliciting information about adverse events that occur in the context of pharmacotherapy. This lack of consensus is not limited to child psychiatry; it extends to adult psychiatry as well as other areas of medicine. Three approaches have been described: the use of an open-ended general inquiry; the use of general inquiry augmented by a set of drug-specific queries or checklist; or the use of a detailed review of body systems (21). At the center of this debate are concerns about sensitivity, specificity, and efficiency.

   The use of a detailed review of systems by an experienced clinician is unlikely to miss adverse effects of medication (high sensitivity). However, some experts express concern that this method may produce an unacceptably high number of false-positive responses. If true, this low specificity would come at a great cost in clinician time, and contribute to a greater number of unnecessary medication changes.

   On the other hand, the open-ended general inquiry gives the parent and child an opportunity to express any concern that may have emerged since starting the medication or since the last visit. Based on the assumption that parents and children will notice important changes in behavior and/or health status, responses to the open-ended inquiry are likely to be clinically meaningful—even if they are not drug related. Because parents and children may not detect subtle adverse effects, the high specificity may result in missed adverse events (low sensitivity).

   A multisite study compared general inquiry, drug-specific queries, and review of systems approach in 60 children on various medications. The study showed that the review of systems approach did indeed identify adverse effects that the other methods missed. Moreover, in approximately a third of cases, the identified adverse effect from the review of systems interview led to an alteration in dose. Nonetheless, the review of systems used in the study was time-consuming and unlikely to be adopted in busy clinical practice (22). Thus, appropriate clinical practice entails the use of open-ended questions, followed by drug-specific queries. In the pages that follow, we list the adverse effects associated with each of the medications presented. Additional safety concerns are also presented in the tables. Other fundamental issues to be covered in

contemporary medication management of children include questions about concomitant medications, concurrent illness, and other medical contacts since the previous visit. The need for vital signs, height, and weight monitoring, for neurologic examination, electrocardiogram, laboratory tests, and drug levels, are medication specific and described in the appropriate sections below.

5. *The Role of Caregivers and the Meaning of Medication*. Collaboration and successful engagement of the child's family are critical to the success of treatment interventions, pharmacologic or otherwise. A detailed discussion with the parents and the child concerning the recommended medication, and an examination of the alternative treatments are prerequisites for initiating psychopharmacologic treatment. In addition, the family and the child should be (to the extent possible) active partners in the treatment process (23). Once chosen, the dose schedule, potential adverse effects, anticipated magnitude of response on target symptoms as well as the time to effect warrant explicit review. This discussion gives an opportunity to evaluate and temper unrealistic expectations about the medication. Depending on the medication, it may be necessary to establish a contingency plan to manage specific adverse effects prior to their occurrence, such as being prepared to start benztropine for a child who develops dystonia when started on a potent antipsychotic such as haloperidol, or to discontinue medication if excessive weight gain is experienced on an atypical antipsychotic. Children, and to some lesser extent adolescents, are dependent on their parents to administer medications, so that parental endorsement of the treatment plan is both ethically sound and practical. Failure to involve parents in the decision-making process may threaten treatment compliance, which in turn may undermine the success of the intervention. Attention should also be paid to the meaning that taking medication has for the child and family (24), in the context of their cultural beliefs and attitudes toward medication. Consideration and exploration of these aspects may reveal a sense of failure on the part of the child or family. Some children may express concern that having to take medication implies that they are crazy or "weird." These issues should be identified and addressed prior to initiating treatment. Even when handled prior to treatment, however, these issues often reemerge and require attention over the course of treatment.
6. *Psychopharmacology in Context, and the Combination of Therapeutic Modalities*. Psychotropic medications, no matter how effective, are often but one element in a multimodal treatment plan that includes other individually tailored interventions. This guiding principle, which may seem self-evident to clinicians accustomed to using various therapeutic approaches in their practice, has become a focal point for research and practice guidelines. For example, practice parameters often provide guidance of selection and sequence of interventions, such as when to use one modality (behavioral therapy or medication) versus a combined medication approach. Several cognitive-behavioral treatments have proven efficacy and should not be overlooked in the

treatment of children and adolescents with major psychiatric conditions (25). Three large-scale, National Institute of Mental Health (NIMH) sponsored, multisite studies in pediatric samples with ADHD (3), depression (13), and OCD (26) have been completed and provide some insight into the use of combined treatments (see following).

7. *Empirically Informed, Evidence-Based Clinical Decision-Making*. A final principle is that treatment plans should be grounded on available empirical evidence. As the database of pediatric psychopharmacology expands, the value of this principle will become even more pressing and places a higher demand for clinicians to stay apace of research findings. The International Association for Child and Adolescent Psychiatry and Allied Professions provides levels of evidence for efficacy of psychotropic medications in children (<18 years) (27). The strength of the evidence relates to the following: type I (strong evidence from at least one systematic review of multiple well-designed randomized controlled trials); type II (strong evidence from at least one properly designed randomized controlled trial); type III (evidence from well-designed trials without randomization, single group, pre–post, cohort, time series or matched case-control studies); type IV (evidence from well-designed nonexperimental studies from more than one center or research group); type V (opinions of respected authorities, based on clinical evidence, descriptive studies, or reports of expert committees) (28). As examples relevant to pediatric psychopharmacology, type I evidence exists in the case of: methylphenidate and dexmethylphenidate, amphetamines, atomoxetine, clonidine, guanfacine for ADHD; clonidine, haloperidol, risperidone, and pimozide for Tourette disorder; fluoxetine and escitalopram for major depression; sertraline for OCD, generalized anxiety disorder (GAD), and social phobia (SP); fluvoxamine for GAD and SP; risperidone for bipolar disorder; risperidone and aripiprazole for agression. Type II evidence exists in the case of: fluoxetine, fluvoxamine, and clomipramine for OCD; fluoxetine for GAD and SP; sertraline and citalopram for major depression; haloperidol for psychosis; risperidone, quetiapine, aripiprazole, olanzapine for schizophrenia; quetiapine, aripiprazole, olanzapine, valproate for bipolar disorder; lithium and valproate for aggression. Type III evidence exists in the case of lithium for bipolar disorder. Type IV evidence is not well represented in psychopharmaceuticals for children. Type V evidence exists in the case of carbamazepine, oxcarbazepine for bipolar disorder; lamotrigine for bipolar depression, and venlafaxine for major depression.

This ranking system clearly reflects the state of the science at a particular point in time. Given the rapid pace of development in pediatric psychopharmacology, clinicians have a responsibility to remain up to date with the empirical evidence to ensure the best possible match between target symptoms and treatment options.

6.1.4 SPECIFIC MEDICATION TREATMENTS

CHAPTER 6.1.4.1 ■ ADHD: STIMULANT AND NONSTIMULANT AGENTS

MICHAEL H. BLOCH, CHAD BEYER, ANDRéS MARTIN, AND LAWRENCE SCAHILL

STIMULANTS

Clinical Applications and Empirical Support

The stimulants, especially the short- and long-acting forms of methylphenidate and various preparations of amphetamine, are first-line treatments for attention-deficit hyperactivity disorder (ADHD). In its classic form, ADHD is characterized by inattention, impulsiveness, and hyperactivity, though current convention includes primarily inattentive and impulsive/hyperactive subtypes (1). Epidemiologic studies indicate that ADHD is relatively common in childhood, affecting 2% to 10% of school-age children (2,3). Boys are affected more often than girls. It persists into adolescence in a majority of cases (4), and into adulthood in as many as 30% to 40% of cases (5). Studies of clinical populations indicate that the symptoms of ADHD are among the most common reasons for referral of children to mental health agencies (6). Nonetheless, there is also a substantial number of affected children who do not receive treatment (7). Given the high prevalence of ADHD in school-age children, the potential for long-term functional disability and the high health-related costs associated with the disorder (8), ADHD is a major public health concern. To ensure fewer children with ADHD are missed, the DSM-5 states that several of the ADHD symptoms must be present prior to 12 years of age, compared to 7 years of age in the DSM-IV. This is in keeping with there being no clinical difference found between children identified before or after age 7 years in terms of course, severity, outcome, or treatment response.

The most commonly used stimulants for the treatment of ADHD include methylphenidate, dextroamphetamine, and the mixed preparation of D,L-amphetamine and their derivatives. Table 6.1.4.1.1 outlines the characteristics of psychostimulant medications commonly used to treat ADHD. The empirical basis for the use of stimulants in children with ADHD rests on findings from hundreds of short-term, randomized, placebo-controlled studies conducted over the past 30 to 40 years. Results from controlled studies over the last decade provide additional information about dose response, similarities and differences in response across stimulant preparations, and the importance of regular clinical monitoring to achieve optimal response. Rapport et al. (9) conducted a dose–response study in 76 subjects (66 boys and 10 girls) between the ages of 6 and 11. The 5-week study used four dose levels of methylphenidate (5, 10, 15, and 20 mg given bid) and placebo given in random

order in a cross-over design. All dose levels of active medication were superior to placebo. In addition, there was a clear linear trend, such that classroom behavior and the number of completed assignments improved with each increase in dose. However, the incremental improvement was smaller as the dose moved above the 10-mg dose level. Meta-analysis shows in parallel-group and cross-over trials participants in the active treatment group, compared with the control group, were more likely to report trouble sleeping, report a decrease in appetite and weight, weigh significantly less and have a lower body mass index, and have a higher pulse, have tics or nervous movements, compulsive acts, obsessive thinking, and overly meticulous behavior. They were less likely compared with the control group to report anger, behavioral complaints, or an increase in appetite (10).

In order to compare methylphenidate and D-amphetamine, a placebo-controlled cross-over study was conducted in 48 boys between 6 and 12 years of age (11). Subjects were treated with methylphenidate, D-amphetamine, or placebo in random order for 3 weeks in each treatment condition. During each condition, the dose was increased on a weekly basis (e.g., methylphenidate doses for children under 30 kg of body weight were 12.5, 20, and 35 mg at breakfast and lunch time for the respective weeks). Based on a global rating of response, there were similar levels of response between the two stimulant classes, with 79% of the subjects showing a positive response to methylphenidate and 88% showing a positive response to D-amphetamine. Only 2 of the 48 subjects failed to respond to either stimulant.

TABLE 6.1.4.1.1

STIMULANT MEDICATIONS FOR ATTENTION-DEFICIT HYPERACTIVITY DISORDER

Drug Name (Brand)	Active Ingredient	Onset of Action	Duration of Effect	Required Number of Doses/Day	Suggested Dosing and Titration
Short Acting					
Ritalin® Methylin® Focalin® Metadate®	Methylphenidate	20–60 min Peak effect: 2 hrs	3–6 hrs	2–3 doses; occasionally 4 doses	Start with one 5-mg tablet (2.5 for Focalin®) 2–3× a day. Increase by 5 mg (or 2.5 mg for Focalin®) until target behavior controlled
Dexedrine® Dextrostat®	D-amphetamine	20–60 min Peak effect: 1–2 hrs	4–6 hrs	2–3 doses	Start with one 5-mg tablet 2–3× per day[a]
Adderall®	D,L-amphetamine	30–60 min Peak effect: 1–	4–6 hrs	2–3 doses	Start with one 5-mg tablet

		2 hrs			2–3× per day[a]
First Generation: Long Acting					
Ritalin SR® Metadate ER® Methylin ER®	Methylphenidate	60–90 min Peak effect: 8 hrs	5–8 hrs	1–2 doses	Start with one 10-mg tablet 1–2× per day[a]
Dexedrine Spansules®	D-amphetamine	60–90 min Peak effect: 8 hrs	6–8 hrs	1–2 doses	Start with one 5-mg capsule 1–2× per day[a]
Second Generation: Long Acting					
Concerta®	Methylphenidate	30 min–2 hrs	12 hrs	1 tablet	Start with one 18-mg tablet once per day[a]
Metadate CD® Ritalin LA®	Methylphenidate	30 min–2 hrs	6–8 hrs	1–2 capsules	Start with one 10-mg capsule once per day[a]
Daytrana®	Methylphenidate	20–60 min Peak effect: 10 hrs after single application, 8 hrs after repeat applications	8–12 hrs	1 patch	Start 10-mg patch worn 9 hrs daily. Maximum dose: 30 mg patch worn 9 hrs daily
Focalin XR®	Dexmethylphenidate	1–4 hrs	8–12 hrs	1 capsule	Start with one 5-mg capsule once per day[a]
Quillivant XR®	Methylphenidate	30 min Peak effect: 5 hrs	8–12 hrs	1 liquid dose	Start with 20 mg liquid suspension once per day[a]
Adderall XR®	D,L-amphetamine	1–2 hrs	10–12 hrs	1 capsule	Start with one 5- or 10-mg capsule once per day[a]
Vyvanse®	L-lysine-dextroamphetamine	2 hrs Peak effect: 3–4 hrs	10–12 hrs	1 capsule	Start with one 30-mg capsule once daily[a]

[a]Titrate upward until target behavior controlled.

Pelham et al. (12) compared the extended-release methylphenidate product,

Concerta, to immediate-release methylphenidate and placebo in a cross-over trial. Sixty-eight children between 6 and 12 years were assigned to receive placebo, immediate-release methylphenidate, or the extended-release methylphenidate in random order. All children were on methylphenidate prior to enrollment. Thus, each child was assigned to a dosage level that was similar to the pretrial dose. The three dose levels for immediate-release methylphenidate were 5 mg three times per day, 10 mg three times per day, or 15 mg three times per day. Each dose level of immediate-release methylphenidate was matched to a similar, though slightly higher, dose of extended-release. Specifically, the dose levels of extended-release were 18, 36, and 54 mg given as a single morning dose. Each treatment (immediate release, matching dose of extended-release, or placebo) was given in random order for 1 week. Both active treatments were superior to placebo, with approximately 50% improvement on both parent and teacher measures of ADHD symptoms. There were no detectable differences between immediate- and extended-release methylphenidate preparations with respect to efficacy or adverse effects.

There are few studies examining long-term use of stimulants (6). A longitudinal cohort from birth to a mean age of 17.2 analyzed 379 children with research-identified ADHD. Of these children, 283 were treated with stimulants, with an average duration of treatment of 33.8 months (13). Nearly 75% of treatment episodes involving stimulants were associated with a favorable response (74.6% for methylphenidate (MPH) and 74.9% for dextroamphetamine). 22.3% of the 283 children experienced at least one side effect during treatment, with gender not being significantly associated with likelihood to develop side effects. Treatment episodes with dextroamphetamine were significantly more likely to be associated with a side effect compared to methylphenidate (10.0% vs. 6.1%; OR, 1.8; 95% CI, 1.1–3.0; p = 0.034). The occurrence of side effects of dextroamphetamine was independent of dose, while the occurrence of side effects with MPH showed dose dependence. Additionally, side effects occurred most frequently at either tail end of age distribution with both MPH and dextroamphetamine.

With its sample size of 576 children, the Multimodal Treatment Study of children with attention-deficit/hyperactivity disorder (MTA) provides convincing evidence for the long-term benefits of methylphenidate. In the MTA study, children between 7 and 10 years of age were randomly assigned to one of four treatment groups: medication management (N = 144; primarily methylphenidate administered in a systematic fashion with close monitoring); an intensive behavioral treatment program (N = 144); combined medication management and the same behavioral treatment program (N = 145); or community care, which served as the control group (N = 146). The MTA research sites provided treatment to three of these groups, including the medication management group, the behavioral therapy-only group, and the combined medication plus behavioral therapy group. The community care group received treatment from self-selected practitioners. In most cases (84 of 146, or 58%),

community care consisted of methylphenidate given on a twice-daily schedule. After 14 months of treatment, all four groups showed improvement compared to baseline. Comparisons across the four groups showed that the combined treatment group and the medication management group did significantly better than the community care group and the behavioral treatment-only group across a range of outcomes.

Several potentially important differences emerged when community care was compared to medication management provided by the MTA sites. First, community practitioners most often administered methylphenidate on a twice-daily schedule, compared to three times per day in the MTA-treated groups. Second, among the children randomly assigned to community care, 33% (N = 48) stopped taking medication during the study period. Not surprisingly, this group showed the least improvement on the primary outcome measures. By contrast, only 3% (N = 18) of the research medication management groups (both medication-only and medication plus behavioral treatment) discontinued medication during the study. Third, in the MTA medication management groups, follow-up visits were more frequent and parent and teacher ratings were used in a systematic way to inform clinical decision-making. Fourth, methylphenidate in general was dosed lower in the community care group compared to the medication management groups in MTA, suggesting that most community prescribers may be underdosing the stimulants.

Taken together, the results of these studies suggest that stimulants are effective for short- and long-term treatment of children with ADHD. When considering group effects, stimulants appear to be equally beneficial, but individual patients may respond better to one preparation over another. The modest effectiveness of stimulants observed in the community care group of the MTA suggests that close clinical monitoring with dose adjustments based on systematic assessment of therapeutic and side effects contributes to compliance and optimal results.

Mechanism of Action

Although stimulants have become the standard treatment for ADHD, their mechanism of action is not clearly understood. In addition, the mechanism of action for amphetamines and methylphenidate may be slightly different (14). Methylphenidate promotes the release of stored dopamine and blocks the reuptake of dopamine at presynaptic dopamine transporter sites. Amphetamines also block dopamine reuptake at the transporter, but appear to promote the release of newly synthesized dopamine more selectively. These combined effects enhance dopamine function in the striatum and, at least indirectly, in the prefrontal cortex (PFC). It is also clear that both methylphenidate and the amphetamines affect the norepinephrine (NE) system (15). For example, both compounds decrease the neuronal firing rate in the locus coeruleus (LC), although amphetamine appears to be more potent in this action. Whether the effect on the NE system is facilitatory or inhibitory is not clear at present.

Nonetheless, these combined effects appear to be essential to the clinical effects of the stimulants, as drugs with more selective action (guanfacine or desipramine) tend to have smaller clinical effects.

Pharmacokinetics

The pharmacokinetics of all individual currently available stimulant medications for ADHD is outlined in Table 6.1.4.1.1. Immediate-release formulations of methylphenidate, dextroamphetamine, and the combined levo- and dextroamphetamine preparation are readily absorbed and show behavioral effects 30 to 60 minutes after ingestion. The peak level of immediate-release methylphenidate occurs approximately 90 to 150 minutes after ingestion and the clinical effects last 3 to 5 hours. The immediate-release amphetamine products achieve peak levels between 1 and 3 hours, with duration of action of 5 to 7 hours. Based on blinded studies in a research classroom setting, the D,L-amphetamine preparation appears to have a slightly longer duration of action than standard D-amphetamine (16). Methylphenidate and amphetamine are metabolized in the liver, but by quite different pathways (see previous chapter for more details). For the immediate-release formulations of these stimulants, the parent compound and metabolites are excreted in the urine within 24 hours. Several sustained-release (SR) products have been introduced, offering a range of options for clinical management of children and adolescents with ADHD, often with once-a-day dosing. These extended-release formulations have been increasingly utilized based on convenience rather than improved efficacy.

Specific Stimulants and Clinical Management

There has been considerable debate over whether stimulant dose should be weight based or a fixed dose (17). At least in part, this controversy can be traced to early research suggesting that lower doses, such as 0.3 mg/kg/dose, were optimal for enhancing cognitive performance, whereas higher doses (0.6 mg/kg/dose or higher) were more effective for behavioral control (18). Subsequent studies have not supported this view. For example, a convincing linear dose–response was demonstrated across a range of outcomes in a placebo-controlled, cross-over study involving 76 children and four dose levels of methylphenidate (9). Nonetheless, individual children may indeed show variability in response across a range of dose levels. Other children may show an orderly dose–response up to a threshold, above which there is little additive benefit. Thus, the mg/kg calculation can be used as a crude guide to calculate the starting dose of 0.3 mg/kg/dose and to a usual ceiling dose (e.g., 0.8 mg/kg/dose). Thereafter, the dose can be increased to establish an optimal response. For example, school-age children can be started on 5 mg tid (just

before breakfast, just before lunch, and 3 to 4 pm). The dosage may be increased to 10 mg bid (morning and noon) and 5 mg after school after 5 to 7 days. Subsequent increases are based on clinical response and emergence of adverse effects. The third dose typically remains half (or even less) of the first and second doses so as to minimize *rebound* effects and possible interference with sleep (17).

To determine the optimal daily dose of methylphenidate, it is essential to get feedback from both parents and teachers. In the MTA study, children were seen weekly when starting the medication to monitor progress and side effects. The study used daily ratings to assist with the assessment of response. Although this is not always feasible in clinical practice, clinicians may elect to pace dose increases with the collection of parent and teacher ratings. For example, in the first month of treatment, clinicians may increase the dose on a weekly basis. Collection of parent and teacher ratings prior to each increase would allow comparisons across dose levels. This information could be integrated with side-effect data in order to select the optimal dose.

A similar approach can be used with D-amphetamine and D,L-amphetamine. The dosing of these two drugs is similar and both have approximately twofold greater effect compared to methylphenidate. Thus, the amphetamines are administered at half the methylphenidate dose. Moreover, due to their slightly longer duration of action, the amphetamines are typically given twice a day—morning and noon. The initial dosage may be a single 2.5-mg dose in younger children or a 5-mg dose in older children. After 5 to 7 days, the medication may be raised 5 mg bid in younger children and 10 mg bid in older children. Thereafter, the dosage may be raised every 5 to 7 days to a total of 15 to 20 mg/day in younger children, and 40 mg/day in older children.

Several extended-release products—formulated with methylphenidate (Concerta, Aptensio, Daytrana transdermal patch, Metadate CD, Metadate ER, Methylin ER, Ritalin LA, Ritalin SR, Quillivant XR; Focalin XR [dexmethylphenidate]) and amphetamine (Adderall XR [dextroamphetamine], Dexedrine-Spansule [dextroamphetamine sulfate], Evekeo [amphetamine sulfate], Vyvanse [lisdexamfetamine]) are available. These longer-acting preparations are as effective as the immediate-release compounds and show similar side-effect profiles (13,19,20). The advantage of the long-acting preparations is that children do not need to take a dose in school, which may enhance compliance. The longer-duration formulations may minimize the behavioral rebound often seen with immediate-release formulations. Originally developed for children who could not swallow pills, Daytrana (methylphenidate transdermal patch) has been tested clinically on youth from 7 to 16 years, with the patch adhered to intact skin, and it appears as effective as oral preparations.

Adverse Effects

Growth retardation, presumed to be secondary to stimulant-induced appetite suppression, has been a common concern among clinicians and families alike. Based on data from a large cohort of clinic cases treated with stimulants, Spencer et al. (21) contend that slowed growth may be temporary, and that children with ADHD may be shorter than their age mates before puberty, but "catch up" in adolescence. Follow-up data from the MTA study show that children who remained on medication from the end of the 14-month study to the 24-month follow-up did not gain as much in height or weight when compared to the children who were never started stimulant medication. The group that did not receive medication (N = 106) was about 1 cm taller and 1 kg heavier at the 24-month follow-up than the group (N = 222) that was treated with stimulant medication for the entire 2-year period (22). Appetite suppression can often be managed by giving stimulant medications with food, or immediately after meals. Height and weight should be monitored regularly in children treated with stimulants, and tracked during long-term maintenance on growth charts.

Other common side effects include sleep disturbance, depressed mood, stomach aches, headaches, overfocusing on details, tics and mannerisms, and picking at skin. Insomnia can be difficult to sort out, as many children with ADHD have sleep difficulties prior to receiving stimulant medications. Rebound effects associated with stimulant withdrawal may compound pre-existing sleep problems. Thus, the child's sleep history should be documented prior to treatment and monitored throughout. As noted, it is common practice for the third dose of methylphenidate to be lower than the first two in order to minimize a possible rebound effect. The use of clonidine as an aid for sleep has been proposed, yet remains a controversial practice (23). A multisite trial conducted by the Tourette Syndrome Study Group (24) showed that complaints of insomnia were indeed lower in subjects randomly assigned to combined treatment with methylphenidate and clonidine compared to methylphenidate alone.

Results from case reports and controlled studies suggest that exposure to stimulants can be associated with the emergence of tics (25) or the worsening of pre-existing tics (26). However, several studies have also shown that tics do *not* worsen when children with ADHD and comorbid tic disorders are treated with stimulants (and in fact about one-third get better) (24,27,28). Meta-analysis suggests that stimulants are just as effective at reducing ADHD symptoms in children with comorbid tics compared to those without (29). Furthermore, meta-analysis of randomized controlled trials of stimulants for children with ADHD suggests no increased risk of tics with stimulant medication, and that over 6% of subjects reported tics as a side effect of study medication regardless of whether they received stimulants or placebo (30). Exacerbation of existing tics or de novo tics that occur during stimulant use appear to be much more likely to be coincidental than causative.

Nonstimulant Treatments of ADHD

Atomoxetine (Strattera)

Atomoxetine was originally developed for the treatment of depression, but it has never been marketed as an antidepressant. Atomoxetine is a selective NE reuptake inhibitor, a property that it shares in common with desipramine. Unlike desipramine, atomoxetine does not appear to be associated with an increase in QTc interval. Given the efficacy of desipramine for the treatment of ADHD, atomoxetine was evaluated for the same indication. Following the completion of several placebo-controlled trials (31,32), atomoxetine was approved by the FDA as a safe and effective treatment for children and adolescents with ADHD. Atomoxetine may also be useful in the treatment of comorbid oppositional defiant disorder (33,34).

The pharmacokinetics of all nonstimulant medications used to treat ADHD is presented in Table 6.1.4.1.2. The serum half-life of atomoxetine is approximately 4 hours, which implies that the drug would be given at least twice a day. Indeed, initial studies used a twice-daily regimen, but subsequent trials evaluated the efficacy of once-a-day dosing (31,32) and, both dosing strategies have been shown to be superior to placebo and show similar therapeutic benefit (31,32). The improvement of ADHD symptoms is not as robust as with stimulants (35). The total daily dose should fall between 0.8 and 1.2 mg/kg. Doses greater than 1.2 mg/kg/day have no therapeutic advantage (34). Clinicians should start with once-a-day dosing with gradual titration of dose. If the child encounters adverse effects or the benefits are inadequate, a twice-a-day dosing schedule can be considered.

Common side effects of atomoxetine include dyspepsia, nausea, vomiting, fatigue, decreased appetite, weight loss, mood swings, headache, constipation, insomnia, and dizziness (36). Decreased appetite, vomiting, and weight loss are more likely to occur early in treatment and may be attenuated by slow titration of dose. Black box warnings on this drug include hepatitis, increased aggression and hostility, and suicidal thinking (37). Atomoxetine is metabolized by the cytochrome P450 2D6 and thus it is vulnerable to interaction from drugs that inhibit 2D6, such as paroxetine or fluoxetine.

TABLE 6.1.4.1.2

NONSTIMULANT MEDICATIONS FOR ATTENTION-DEFICIT HYPERACTIVITY DISORDER

Medication	Drug Name	Frequency	Daily Dose Range
Atomoxetine	Strattera®	Daily or twice daily	0.5–1.2 mg/kg/day (<70 kg) 40–80 mg/day (≥70 kg)
Clonidine	Clonidine IR®	Twice daily to 4× per day	0.05–0.4 mg/day
	Clonidine ER (Kapvay®)	Daily	0.1–0.4 mg/day
Guanfacine	Guanfacine IR®	Twice daily to 4× per day	0.5–0.4 mg/day
	Guanfacine ER (Intuniv®)	Daily	1–4 mg/day

Desipramine	Norpramin®	Twice daily to 3× per day	2–5 mg/kg/day
Bupropion	Wellbutrin®	Twice daily	50–150 mg

Bupropion (Wellbutrin)

Bupropion is unrelated to all other available antidepressants. Although its mechanism of action is unclear, it appears to have both dopaminergic and noradrenergic effects. It is approved for the treatment of depression and smoking cessation in adults. Although bupropion has not been studied for depression in children or adolescents, it has been evaluated in controlled studies for the treatment of ADHD. A placebo-controlled trial of bupropion in 72 children with ADHD showed its superiority over placebo, although the treatment effect was smaller than that usually seen with stimulants (38). The dose of bupropion (3 to 6 mg/kg/day) ranged from 50 to 200 mg/day in divided doses. The findings of this study are consistent with previous placebo-controlled studies, and a direct comparison-study with methylphenidate (39). In an open-label study conducted in 24 adolescents (ages 11 to 16) with ADHD and depression, sustained-release bupropion was associated with improvements in both conditions in 58% ($N = 14$), in depression only in 29% ($N = 7$), and in ADHD alone in 4% ($N = 1$), suggesting that further studies of this monotherapy appear warranted for patients with these commonly co-occurring conditions (Table 6.1.4.1.2) (40).

Side effects of bupropion include agitation, insomnia, skin rashes, nausea, vomiting, constipation, and tremor. Bupropion may also reduce the seizure threshold in a dose-dependent fashion. The seizure liability of bupropion was first described in a group of female patients with bulimia nervosa. Because of this, regardless of diagnosis, it is recommended that daily doses not exceed 300 mg in children, and no single dose should exceed 150 mg and should not be used in comorbid eating disorders. Bupropion (Wellbutrin) is available in 75- and 100-mg tablets, in 100- and 150-mg SR tablets, and 150- and 300-mg bupropion XL tablets. Treatment is usually on a tid basis for the immediate-release formulation, given the agent's short half-life; bid dosing is possible with the SR preparations and once daily is recommended with XL preparations.

ALPHA-2 ADRENERGIC AGENTS

Clonidine (Catapres, Kapvay) and Guanfacine (Tenex, Intuniv)

The short-acting alpha-2 adrenergic agents (clonidine and guanfacine) have been used in the treatment of ADHD and tics for well over two decades, but were only FDA approved for use in adults with hypertension. More recently, extended-release

forms of both clonidine (Kapvay) and guanfacine (Intuniv) were approved for the treatment of children with ADHD. These long-acting formulations have the advantage of once-a-day dosing and a specific FDA indication for ADHD compared to the short-acting formulations, but represent a significant cost increase compared to the off-patent shorter medications (especially with regard to clonidine).

Clinical Applications and Empirical Support

Meta-analysis has demonstrated that alpha-2 agonists are effective for the treatment of ADHD as monotherapy or as an add-on treatment to stimulants (41). Meta-analysis of 12 randomized controlled trials (including nine monotherapy trials and three add-on trials) demonstrated that alpha-2 agonist monotherapy significantly reduced overall ADHD symptoms (effect size = 0.59), hyperactivity/impulsivity (effect size = 0.56), inattention (effect size = 0.57), and oppositional defiant disorder (ODD) symptoms (effect size = 0.44) or alpha-2 agonists as add-on treatment to stimulants also significantly reduced overall ADHD symptoms (effect size = 0.36), hyperactivity/impulsivity (effect size = 0.33), and inattention (effect size = 0.34) (41). But, not surprisingly, effect sizes were lower for the use of alpha-2 agonists as add-on treatments to stimulants as compared to monotherapy trials (41). Meta-analysis has further suggested that alpha-2 agonists (restricted to short-acting formulations) have a similar effect in reducing ADHD symptoms in children with comorbid tic disorders (effect size = 0.61) (29). Alpha-2 agonists have been demonstrated to significantly reduce tics in meta-analysis of randomized controlled trials (effect size = 0.31). However, there is some evidence to suggest that alpha-2 agonists may be particularly effective in reducing tics in children with comorbid ADHD (effect size = 0.68) and have a much smaller benefit in reducing tics in children without comorbid ADHD (effect size = 0.15) (42). There is no evidence to suggest that there is any difference in efficacy between guanfacine and clonidine derivatives or for that matter, short- or long-acting forms of either medication (29,41,42).

Mechanism of Action

The traditional view is that clonidine regulates central noradrenergic activity through its agonist effects on presynaptic alpha-2 receptors in the locus coeruleus. Clonidine is indeed 10 times more potent than guanfacine in reducing locus coeruleus firing and inhibiting NE release. In addition to weaker presynaptic effects, accumulated data from studies in primates show that guanfacine has direct stimulating effects on postsynaptic alpha-2A receptors located in the PFC (43,44). These animal studies have established that this pharmacologic mechanism improves PFC function. Given the fundamental role of the PFC in attention and working memory, this action is likely to be relevant for the treatment of ADHD.

Clinical Management

Clonidine comes in 0.1-, 0.2-, and 0.3-mg tablets. In school-age children, the starting dose is typically 0.05 (1/2 of a 0.1-mg tablet) at bedtime. The dose is then increased in 0.05 mg increments every 3 to 5 days as tolerated to a maximum of 0.2 mg/day (0.05 mg qid) in prepubertal children, and 0.3 mg in teenagers. To ensure even behavioral effects and thus blood levels across the entire day, clonidine is typically given three to four times per day. Clonidine transdermal patches (Catapres TTS) delivering 0.1, 0.2, and 0.3 mg/day are also available. Extended-release formulations of clonidine (Kapvay) are available in doses of 0.1, 0.2, or 0.3 mg and can be given once per day. However, it is generally recommended to give daily doses of greater than 0.2 mg divided into two doses daily. The typical starting dose of guanfacine is 0.5 mg at bedtime, with 0.5 mg increases every 3 to 5 days to a total of 1.5 to 4.0 mg/day into two divided doses. Guanfacine ER can be given once per day in similar total daily doses (2 to 4 mg) to short-acting guanfacine and titrated in a similar rate (every 3 to 5 days). Guanfacine ER is available in doses of 1, 2, 3, or 4 mg.

Adverse Effects

The adverse effects of clonidine and guanfacine are similar, though guanfacine appears to be better tolerated. The most common side effects include sedation, dizziness, irritability (especially when the medication wears off), and midsleep awakening. Hypotension is generally not a problem with either drug in children and adolescents, but warrants monitoring, particularly in the dose-adjustment phase. A related concern with clonidine is the well-documented phenomenon of rebound hypertension following precipitous withdrawal (45). In adults with high blood pressure, however, abrupt discontinuation of guanfacine did not result in rebound hypertension (46). Nonetheless, abrupt discontinuation of either drug should be avoided.

CHAPTER 6.1.4.2 ■ ANTIDEPRESSANTS

MICHAEL H. BLOCH, CHAD BEYER, ANDRéS MARTIN, AND LAWRENCE SCAHILL

The antidepressants include a group of chemically diverse compounds that have been shown to be effective in the treatment of adults with major depression. Some of these medications have been used, and are effective, in the treatment of a variety of other disorders, including obsessive–compulsive disorder (OCD), anxiety disorders, premenstrual dysphoric disorder (PMDD), and posttraumatic stress disorder (PTSD). Antidepressants can be classified according to (1) chemical similarity (such as tricyclic compounds, and within these, secondary or tertiary amines); (2) primary mode of action (such as the selective serotonin reuptake inhibitors [SSRIs], selective norepinephrine reuptake inhibitors [SNRIs], or monoamine oxidase inhibitors); and (3) miscellaneous, newer antidepressants (such as bupropion, vortioxetine, trazodone, vilazodone, or mirtazapine). The SSRIs are by far the most extensively used antidepressant class in children and adolescents, and the class with the best empirical support.

SELECTIVE SEROTONIN REUPTAKE INHIBITORS

The SSRIs are a group of chemically unrelated compounds that potently inhibit the reuptake of serotonin into presynaptic neurons. Currently marketed SSRIs include fluoxetine, sertraline, paroxetine, fluvoxamine, citalopram, and escitalopram. In contrast to tricyclic agents such as desipramine which inhibit the reuptake of both norepinephrine and serotonin, these compounds are far more selective for serotonin.

Clinical Applications

All of the SSRIs in current use are approved for use in the treatment of adults with OCD. With the exception of fluvoxamine, the SSRIs are also approved for use in adults with major depression. Table 6.1.4.2.1 depicts the current FDA-approved antidepressants for use in the pediatric population. In general, the use of antidepressants in children has not been limited to their FDA-approved uses as lack of FDA approval is typically indicative of lack of research in the area rather than lack of efficacy. Furthermore, there is limited data to suggest at least within antidepressant classes that individual medications differ in efficacy.

Empirical Support

The introduction of the SSRIs, starting with fluoxetine in the late 1980s, has had a dramatic impact on the practice of pediatric psychopharmacology. Compared to the

tricyclic antidepressants (TCAs), monotherapy with the SSRIs is relatively simple. As a group, these medications are generally well tolerated, with a superior side effect profile to TCAs, with less anticholinergic action can typically be given once a day, do not prolong the QTc interval, therefore require blood-level monitoring or ECGs and, unlike TCAs, are not fatal in overdose (1,2). Following the early clinical trials with clomipramine and fluoxetine in children and adolescents (3–5), several large placebo-controlled clinical trials with sertraline (6) and fluvoxamine (7) in OCD; with fluoxetine (8) and paroxetine (9) in depression; and with fluvoxamine in non-OCD anxiety disorders (10) have been conducted in pediatric populations. In each of these studies, the SSRI was superior to placebo in the primary outcome measure of interest. Trials comparing the relative efficacy of SSRIs, cognitive behavioral therapy (CBT), and their combination have been completed with fluoxetine for depression (11), and with sertraline for OCD (12).

Obsessive–Compulsive Disorder

Clomipramine was the first agent approved by the FDA for use in pediatric OCD in 1989. Several SSRIs have been approved since for the treatment of OCD, following multisite, randomized, placebo-controlled trials. These include sertraline, fluvoxamine, fluoxetine, and paroxetine (7,13–15), with highly significant pooled effects versus placebo, and an overall effect size of 0.46 which correlates with a difference in score of 4 points on the Children's Yale-Brown Obsessive–Compulsive Disorder Scale (CYBOCS). Additionally, pairwise comparison in meta-analysis reported clomipramine as having a significantly greater standard–mean difference than the SSRI ($p = 0.002$, chi-square test), which remained significant when the year of study was accounted for (16). The four SSRIs did not differ from one another in efficacy compared to placebo.

Taken together, these data suggest that the SSRIs are effective for the treatment of OCD in children and adolescents. However, some children with OCD may show only a partial response to an adequate trial of an SSRI. For example, approximately 40% of the subjects in the multisite sertraline study showed less than a 25% improvement in obsessive–compulsive symptoms (6). This observation indicates that clinicians should remind parents and patients not to have unreasonably high expectations for SSRI treatment and the importance of combined treatment with CBT. The problem of partial response raises questions about whether to switch to another SSRI or clomipramine, or to embark on one of several medication augmentation strategies. Although not well studied in children (17), two studies have shown that the addition of low-dose haloperidol (18) or risperidone (19) to an SSRI can be effective in adults with refractory OCD. A recent meta-analysis provides support for augmentation of SSRIs with haloperidol and risperidone in the treatment of adults with OCD (20). In light of the inadequate support for combined pharmacotherapy in

children with refractory OCD, other interventions should be considered, particularly CBT.

Abbreviations: O, obsessive-compulsive disorder; D, major depressive disorder; P, posttraumatic stress disorder; G, generalized anxiety disorder; S, social anxiety disorder; N, panic disorder.

Indeed, the Pediatric Obsessive Compulsive Treatment Study (POTS) (21) showed the combination of CBT and SSRI treatment to be superior over either monotherapy alone. In that study, 112 children (mean age approximately 11.5 years, with 56 boys and 56 girls) with OCD across three treatment sites were randomly assigned to sertraline, CBT, their combination, or pill placebo. Statistical analyses on the CYBOCS indicated a significant advantage for CBT alone ($p = 0.003$), sertraline alone ($p = 0.007$), and combined treatment ($p = 0.001$) compared with placebo. Combined treatment showed a 53% improvement on the CYBOCS compared to 46% for CBT alone, 30% for sertraline alone and 15% for placebo. These results suggest that CBT, if readily available, may be the preferred first treatment for OCD, either alone or in combination with an SSRI. The two groups who were treated with active medication each started on a dose of 25 mg/day with gradual increases to a maximum of 200 mg/d. The combined treatment group received an average of 133 mg/day compared to 170 mg/day for the sertraline-only group.

Based on the demonstrated efficacy and safety of the SSRIs in children and adolescents with OCD, these medications are commonly used to reduce repetitive

behavior in pervasive developmental disorders (PDDs) (22). Despite their common use in clinical practice, however, the SSRIs have not been well studied in children with PDD. Moreover, the best available evidence indicates that the SSRIs may only be moderately effective for this indication.

Obsessive–Compulsive Behavior in Autism Spectrum Disorders

Evidence is at best mixed for the efficacy of SSRIs for the treatment of obsessive-compulsive symptoms and repetitive behaviors in children with autism spectrum disorders (ASD).

King et al. (23) of the STAART group conducted an NIH-sponsored, multisite study comparing citalopram to placebo in a 12-week parallel group study. One hundred and forty-nine patients with ASD and high levels of repetitive behavior were randomized to either receive citalopram or placebo. They reported no significant difference in the proportion of CGI-I responders at 12 weeks between the citalopram and placebo groups. Additionally, they reported no significant difference in score reduction on the children's yale-brown obsessive-compulsive scale–pervasive developmental disorders from baseline in either the citalopram or placebo treatment groups.

Carrasco et al. (24) conducted a meta-analysis examining the efficacy of serotonin reuptake inhibitors (clomipramine, citalopram, fluoxetine) in the treatment of repetitive behaviors in ASD. They found a small, but significant efficacy of SRIs in the treatment of repetitive behaviors in ASD that was likely attributable to publication bias in the literature. They reported no significant effect of type of medication, age of participant; while dosing of SRI and trial methodologic quality were significantly associated with efficacy. Furthermore, they subsequently conducted a meta-analysis examining fluoxetine, fluvoxamine, fenfluramine, and citalopram in the treatment of participants with ASD and repetitive behaviors after a few additional trials were published (25). They reported no evidence of effect of SSRIs in children with autism and no remaining evidence of publication bias.

Depressive Disorders

Fluoxetine, sertraline, paroxetine, and citalopram have each been studied for the treatment of depression in children and adolescents. The landmark fluoxetine study by Emslie et al. (8) was the first to show superiority of an antidepressant over placebo for the treatment of depression in children and adolescents and was subsequently followed by a replication study (26). A placebo-controlled, multicenter trial comparing paroxetine, imipramine, and placebo (27) indicated that paroxetine was superior to placebo, achieving a 63% response rate, compared to 46% in the

placebo group. By contrast, the response rate in the imipramine group was 50%, although this did not reach statistical significance. Imipramine was associated with common TCA side effects and with a high rate of premature discontinuations. Two identical, industry-sponsored trials of sertraline showed superiority over placebo when combined into a single report (28), but failed to differentiate from placebo when analyzed separately. A randomized clinical trial of citalopram has also shown superiority over placebo.

Since these initial trials, there have been several additional studies conducted on a variety of SSRI medications. Overall, there seems to be compelling evidence for the efficacy of SSRIs in the treatment of depression in children. And although meta-analysis has not been able to identify significant differences in efficacy between SSRI agents, fluoxetine appears to have the best evidence of efficacy. Whittington et al. (29) in 2004 reported a favorable risk–benefit profile for some SSRIs, while cautioning that fluoxetine is the only SSRI that they could conclude with certainty as having a beneficial risk–benefit ratio (although there is no evidence of a significant difference in treatment benefit between SSRIs). Hetrick et al. (30) in 2012 also suggested caution in their conclusions, although in keeping with the risks of untreated depression, they recommend fluoxetine as the first choice. Varigonda et al. (31) in 2015 added that treatment gains in pediatric major depressive disorder were greatest early in treatment, and advocate for a minimum of 4 weeks of SSRI treatment, while they did not report a difference between particular SSRI agents. Cipriani et al. (32) in 2016 examined 14 antidepressants, rating the quality of evidence as very low in most comparisons, and that only fluoxetine was statistically significantly more effective than placebo. In addition, fluoxetine was superior to duloxetine and imipramine in terms of tolerability, while imipramine, venlafaxine, and duloxetine had more discontinuations due to adverse effects than in placebo. They caution that the risk–benefit profile of SSRIs is not clearly advantageous with children and adolescents, and emphasize that fluoxetine appears to be the best option.

The largest and most important study to date in this area is the Treatment for Adolescents with Depression Study (TADS) (11). In it, 439 adolescents 12 to 17 of age were randomly assigned to fluoxetine alone, CBT alone, their combination, or pill placebo. They were followed for 12 weeks in the acute phase and for a 6-month extension. Results of the acute phase (12-week trial) showed that combined treatment had the highest rate of positive response (71% for the combined treatment, compared to 61% for medication alone, 43% for CBT alone, and 35% for placebo). The combined treatment group also had a slightly lower rate of suicidal ideation (5.6%) compared to the fluoxetine-only group (8.3%). Fluoxetine alone and fluoxetine with CBT were both superior to placebo. However, combined treatment with fluoxetine and CBT was not significantly better than medication only and CBT alone was not superior to placebo.

Concerns over the increased risk of suicidality among children treated with SSRIs

became paramount, initially garnering substantial attention in the media and lay press, and following extensive review by British and American regulatory agencies, eventually led to their temporary removal (in the United Kingdom) and the introduction of an FDA-mandated *black-box warning* (in the United States) in 2004. The history and full implications of this series of concerns are explored in detail in a review (33) and continue to be a source of controversy, shifting policy, and clinical recommendations. In the context of this general overview of pediatric psychopharmacology, the following are important high points of the discussion to date: (1) A review of all clinical trials (both published and unpublished) using SSRIs in the treatment of children and adolescents with depression and other indications (*N* > 4,400 subjects, across 26 controlled trials, 16 of them for depression) was commissioned by the FDA. It revealed an increased risk in new onset spontaneously reported suicidal ideation between SSRI- and placebo-treated individuals (occurring at respective rates of 4% and 2%), for a risk ratio of 1.95 (95% confidence interval, 1.28 to 2.98) (34), although there was no increase in suicidal ideation when assessed systematically as an item on depression rating scales; (2) all reported events referred to suicidal *ideation,* rather than suicidal attempt or completed suicides; (3) there is compelling pharmaco-epidemiologic data to suggest that paralleling the widespread use of SSRIs in the United States, the suicide rate among those ages 15 to 19 fell from about 11 per 100,000 in 1990 to 7.3 per 100,000 in 2003 and synchronous with the FDA black-box warning on antidepressants and the likely reduction in antidepressant usage in 2004, the suicide rate climbed 14% for those younger than 20, from 1,737 deaths to 1,985 (35); and (4) based on these data, it is important to recommend close monitoring during the initial period after an antidepressant is started. When treatment with an SSRI is opted for, fluoxetine may be generally recommended as the first-line agent because of its FDA indication for depression and a lower reported rate of incident suicidal ideation. Guidelines from the FDA and the American Academy of Child and Adolescent Psychiatry (AACAP) call for intensive monitoring during the early phases of treatment: weekly for the first 4 weeks, once other two weeks for the next month, and monthly thereafter. While such recommendations are clinically sensible, they may actually contribute to increased suicide rates in children and adolescents, in that practitioners may hesitate in using these agents if they are unable to provide the intensive monitoring recommended. This has become especially problematic in underserved areas, where nonspecialists are resource restricted and therefore may be reluctant to prescribe antidepressants to this population.

Non-OCD Anxiety Disorders

Sertraline has been FDA approved for the treatment of generalized anxiety disorder and social phobia, as research in the Children and Adolescents Anxiety Multimodal Treatment study (CAMS) showed it to be effective, especially in combination with

CBT, for the treatment of non-OCD anxiety disorders (36). In this randomized, placebo-controlled trial, 488 children between the ages of 7 and 17 years old with separation anxiety disorder, generalized anxiety disorder, or social phobia were randomized to receive CBT, sertraline up to 200 mg/day, a combination of CBT and sertraline, or placebo for 12 weeks. This study showed 80.7% of participants receiving CBT and sertraline combination therapy improved on the CGI-I scale; 59.7% improved on CBT alone and 54.9% improved on sertraline alone. In this study, they began with 25 mg/day and uptitrated to a daily maximum of 200 mg by week 8. Fluvoxamine has shown efficacy on the Pediatric Anxiety Rating Scale (PARS), although it is *not* FDA approved for non-OCD anxiety disorders in children. In a multisite study sponsored by the National Institute of Mental Health (10), 128 subjects between the ages of 6 and 17 years were randomly assigned to placebo or fluvoxamine after a 3-week psychoeducational intervention. The primary outcome measure was the PARS, a new scale developed specifically for the trial. After 8 weeks of treatment, children in the fluvoxamine group showed a 52% improvement (mean decrease in PARS from 18.7 to 9.0, $p < 0.001$) compared to 16% improvement (mean decrease from 19.0 to 15.9, $p < 0.001$) for the placebo group. The dose began at 25 mg/day, titrated upwards by 25 mg twice a day after 4 days and can continue to be uptitrated in 25-mg increments every 4 to 5 days as tolerated, to a maximum of 200 mg/day. The findings from this study provide support for the efficacy and large effect size of fluvoxamine in the treatment of generalized anxiety disorder, social phobia, and separation anxiety.

Mechanism of Action

The SSRIs inhibit the reuptake of serotonin into the presynaptic neuron by the serotonin transporter located on presynaptic nerve terminals. Over time, this blockade leads to a desensitization of the serotonin autoreceptors, which typically exert an inhibitory influence on serotonin release. With continued receptor antagonism at the transporter, pharmacodynamic tolerance develops as the desensitized autoreceptors do not exert their usual inhibitory influence and an increased receptor firing rate leads to more serotonin being released. Based on a series of animal studies, Blier et al. (38) suggest that the main location of the enhanced serotonergic function appears to be the hippocampus in depression, and the orbital frontal cortex in OCD.

Pharmacokinetics

The pharmacokinetic parameters of antidepressant medications are depicted in Table 6.1.4.2.2. Most SSRIs have relatively long half-lives, permitting single daily dosing. Fluvoxamine, which has the shortest half-life, is given on a twice-daily schedule. A recent pharmacokinetic evaluation of paroxetine showed that children metabolize the

medication faster than adults (38). Despite the shorter half-life in the pediatric population, these investigators still recommend once-daily dosing for paroxetine. At low doses of sertraline, 50 mg/day or less, children may require twice-daily dosing (39). The pharmacokinetic profiles of the other SSRIs in pediatric populations have not been documented. In adults, fluoxetine (48 to 72 hours), citalopram (36 hours), and escitalopram (30 hours) have the longest half-lives of available SSRIs, compared with sertraline (24 hours), paroxetine (24 hours), and fluvoxamine (15 hours). in addition, fluoxetine has an active metabolite (norfluoxetine) with an elimination half-life of 7 to 14 days. Both fluoxetine (primarily norfluoxetine) and paroxetine are potent inhibitors of CYP2D6, which is particularly concerning as the activity of CYP2D6 is decreased in children younger than 12 years of age. As paroxetine and fluoxetine are 2D6 substrates, they inhibit their own metabolism, resulting in nonlinear kinetics at higher doses. Fluvoxamine primarily inhibits CYP1A2 and CYP2C19, but also inhibits CYP2C9 and CYP3A4 to a lesser extent, and CYP2D6 to the least extent. Due to the metabolism of fluvoxamine through oxidative demethylation and oxidative deamination by CYP2D6 and CYP1A2, both of which it inhibits, it also displays nonlinear pharmacodynamics.

TABLE 6.1.4.2.2

CLINICAL GUIDANCE FOR ANTIDEPRESSANT MEDICATIONS UTILIZED IN PEDIATRIC PRACTICE

	Pediatric		Adult		
	Starting Dose (mg/day)	Typical Dose Range (mg/day)	Starting Dose (mg/day)	Typical Dose Range (mg/day)	Half-Life
Selective Serotonin Reuptake Inhibitors					
Citalopram	10	20–40	20	40	20 hrs
Escitalopram	5	10–40	10	20–40	27–32 hrs
Fluoxetine	10–20	20–80	20	20–80	4–6 days
Fluvoxamine	25–50	5–0	100–300	100–300	16 hrs
Paroxetine	10	20–60	10–20	40–60	21 hrs
Sertraline	25–50	100–200	50	150–250	26 hrs
Serotonin Norepinephrine Reuptake Inhibitors					
Venlaflaxine	37.5	150–225	37.5–75	75–375	10 hrs
Duloxetine	40	40–60	20–60	20–80	12.5 hrs
Desvenlafaxine	10	10–100	50	50–400	11 hrs

Atypical Antidepressants						
Bupropion	100		150–300	100–150	150–300	21 hrs
Mirtazapine	7.5		15–45	15	15–45	20–40 hrs
Vilazodone		Not studied		10	10–40	25 hours
Vortioxetine		Not studied		10	10–80	66 hours
Trazodone	25–50		100–150	150	150–300	3–9 hrs
Tricyclic Antidepressants						
Clomipramine	25		50–200	25	100–250	32 hrs
Desipramine	25		50–200	100–200	150–300	12–27 hrs
Nortriptyline	30–50		30–150	100	75–150	18–44 hrs

Treatment gains in the treatment of pediatric major depressive disorder are greatest earlier in treatment, while minimal after 4 weeks of SSRI treatment (31). Additionally, higher doses of SSRIs appear to be more effective in the treatment of major depressive disorder (MDD) in adults, with a plateau of the benefit at 250 mg of imipramine equivalents (50 mg of fluoxetine) (40). Treatment of pediatric OCD shows a similar trend in that the greatest incremental treatment gains are early in treatment with an SSRI, in this way the CYBOCS improvement has a greater rate of improvement between 0 and 2 weeks, in comparison with the lowest rate of improvement between 8 and 10 weeks of treatment (41). In this way, the best-fitting model of SSRI therapeutic response in the treatment of pediatric OCD is logarithmic. The effect of treatment effect by log (week + 1) from the final model was 1.51 (95% CI: 1.14 to 1.87; $p < 0.001$) (42).

Clinical Management

The dosing recommendations for each individual antidepressant medication are depicted in Table 6.1.4.2.2. Each SSRI in also discussed individually in the following section.

Fluoxetine (Prozac) is available in a 10-mg scored tablet, a 20-mg capsule, and in a liquid preparation (20 mg per 5 mL). A typical starting dose for school-age children is 10 mg/day. Given its long half-life, fluoxetine should be titrated slowly (weekly or even at 2-week intervals) to avoid “overshooting” the optimal dose. The usual dose range for children and adolescents is 20 to 40 mg/day, though some children and adolescents may require higher doses (43).

Sertraline (Zoloft) is available in 25-, 50-, and 100-mg tablets that can be easily broken in half; it is also available as an oral suspension (20 mg per 1 mL). Treatment might start with a 12.5 to 25 mg dose, with similar weekly titration to a range between 50 and 150 mg in children. Doses in excess of 50 mg/day may be required in older adolescents due to moderate levels of platelet reuptake inhibition at 50 mg/day. Clinicians should review therapeutic response while titrating the medication to determine whether additional increases are needed, rather than using an automatic dose schedule.

Fluvoxamine (Luvox) is available in 25-, 50-, and 100-mg scored tablets. Treatment usually begins at 25 mg/day and can be titrated by 25 to 50 mg on a weekly basis. The typical dose range is 50 to 200 mg/day. Although a double-blind trial in children and adolescents with OCD used a rapid dose escalation with increases every 3 days (7), the more recent Research Unit in Pediatric Psychopharmacology anxiety study used a slower upward adjustment (10). This study started with 25 mg/day and titrated to 25 mg twice a day within the first week. Thereafter, the dose was titrated in 25-mg steps each week as tolerated, to a maximum of 200 mg/day in children less than 11 years of age. Adolescents may require doses up to the adult maximum of 300 mg/day, whereas female children may achieve therapeutic effect in lower doses.

Paroxetine (Paxil) is available in 10-, 20-, and 30-mg tablets that can be broken in half, as well as in an oral suspension (10 mg per 5 mL). The typical starting dose is 10 mg/day, with weekly increases to a total daily dose of 10 to 40 mg. As paroxetine is neither safe nor effective in children and adolescents, it should not be used in these populations.

Citalopram (Celexa) is available in 10-, 20-, and 40-mg scored tablets, as well as in a liquid preparation (40 mg per 1 mL). In children less than 12 years of age, citalopram should be started as 10 mg/day, with titrating up by 5 mg/day every 2 weeks to a max of 40 mg/day; in children over 12 years of age, citalopram should be started at 20 mg/day, with titrating up by 10 mg/day every 2 weeks to a maximum of 40 mg/d. In both cases, dosages above 40 mg/day increase the risk of QT prolongation so should be avoided.

Escitalopram (Lexapro) is available in 10- and 20-mg scored tablets, and has type I evidence of efficacy in MDD, although it is not recommended in younger children. In the treatment of adolescents, the recommended dose is 10 mg once daily, with the possibility of increasing to a maximum dose of 20 mg after 3 weeks of treatment.

Adverse Effects

As a group, the SSRIs are generally well tolerated, and potentially serious side effects such as alterations in cardiac conduction times or seizures have not often been reported in the usual dose range. In addition to their propensity for cytochrome

P450–based drug interactions, common side effects of the SSRIs in children and adolescents appear to be behavioral activation and GI complaints such as nausea or diarrhea. Signs of behavioral activation include motor restlessness, insomnia, impulsiveness, disinhibited behavior, and garrulousness. These may occur early in treatment, with dose increases (44) or following the addition of drugs that inhibit the metabolism of the SSRIs (e.g., cimetidine inhibiting CYP2D6 leading to toxicity of CYP2D6 substrates such as fluoxetine or paroxetine). The potential for behavioral activation early in the treatment underscores the importance of starting at low doses and moving upward slowly. As with other antidepressants, hypomania and mania have also been reported, and peripubertal children may be at especially heightened risk (45). Other adverse effects include diarrhea, nausea, heartburn, decreased appetite, and fatigue. Sexual side effects, such as erectile dysfunction, delayed ejaculation, or anorgasmia, all of which are relatively common in adults, should also be considered in adolescents.

Despite the FDA black-box warning regarding the risk of increased suicidal ideation and behavior in children treated with antidepressants, there is actually fairly modest evidence regarding worsening suicidal ideation or behavior with SSRI that is confined to spontaneous reporting of symptoms rather than systematic assessment of suicidality. As with all antidepressants, particularly when treating depression, clinicians should interrogate and monitor for morbid thought, suicidal ideation, and behavior; as well as the potential risk for these in any child or adolescent treated with an SSRI. In the most recent update on the use of SSRIs and SNRIs in children and adolescents by Garland et al. (46), they draw from five high-quality studies to conclude that SSRI significantly decreases suicidal ideation and suicide attempts in young people; additionally, another two high-quality reviews are drawn on to show that population studies demonstrate an inverse correlation between antidepressant use and youth suicide, and an analysis of over 15,000 postmortems in two separate studies have failed to show a relationship between SSRI use and youth suicide.

The incidence of sexual dysfunction as a side effect of SSRI treatment can range between 15% and 80% in adult studies (47) with citalopram decreasing libido in 54%, having delayed orgasm in 36% and erectile dysfunction in 37% of males in the STAR*D study (48). There is a scarcity of research into adolescent sexual dysfunction in the treatment with SSRIs, with a meta-analysis finding that although nonsexual SSRI-induced adverse effects seem to be similar in adult and adolescent populations, sexual dysfunction is poorly reported in the literature. In 11 years, only eight MedWatch reports regarding SSRI-induced sexual dysfunction in adolescents have been filed (49). In adults, meta-analyses have shown bupropion to be associated with a lower rate of treatment-emergent sexual dysfunction than seen with escitalopram, fluoxetine, paroxetine, or sertraline (50) and that mirtazapine is less likely to cause sexual side effects than other antidepressants (51).

SSRI Discontinuation Syndrome and Duration of Therapy

A flu-like syndrome characterized by dizziness, moodiness, nausea, vomiting, myalgia, and fatigue is common following the withdrawal or acute discontinuation of shorter acting SSRIs (or SNRIs) such as paroxetine, fluvoxamine, venlafaxine, and sertraline (52). Recently, a controlled discontinuation study in 220 adults compared the withdrawal effects of fluoxetine, paroxetine, and sertraline: Paroxetine and sertraline were associated with irritability, agitation, fatigue, insomnia, confusion, dizziness, and nervousness upon abrupt withdrawal, but fluoxetine was not (53). The long half-life of norfluoxetine presumably results in a gradual “auto-taper,” even when the oral dose is stopped abruptly. Based on these results, a slow withdrawal of the shorter-acting SSRIs is warranted. Citalopram has a 33-hour half-life, with active metabolites such as desmethylcitalopram and evidence of mild and transient (54) adverse effects following abrupt withdrawal, sudden discontinuation of citalopram should be avoided, but it is unlikely to elicit a full discontinuation syndrome if this occurs.

Another clinical issue that often arises in the course of treating children and adolescents with an SSRI is the duration of treatment required for continued remission of symptoms. Treatment of MDD should have three distinct phases with different aims. The Acute Phase of treatment, wherein remission is induced (minimum of 6 to 8 weeks in duration), is followed by the Continuation Phase wherein remission is preserved and relapse prevented (usually 16 to 20 weeks in duration), ending in the Maintenance Phase wherein susceptible patients are protected against recurrence or relapse (the duration of this phase will vary with the frequency of previous episodes). A basic approach would aim for 1-year total treatment time for a first episode, 2 years if a relapse occurs, and lifelong treatment is likely to be required for MDD that relapses recurrently in the setting of optimal treatment and management. For OCD and anxiety disorders, however, the number of treatment sessions, their length, and the duration of an adequate trial have not been established, but expert consensus recommends 13- to 20-weekly sessions as an adequate trial in most patients (55). A review on OCD suggests discontinuation after a relatively symptom-free period of 8 to 12 months (56). A long-term follow-up study of children and adolescents with OCD (N = 54) found that 70% (n = 39) remained on medication for more than 2 years (57) and persistence of OCD through late adolescence and into adulthood is estimated to occur in about 40% of subjects (58). Given the potential for chronicity in OCD, children and parents should be informed that symptoms may return following a therapeutic reduction or discontinuation of the SSRI.

Drug Interactions

Due to their multiple clinical applications, ease of use, and perceived safety, the

SSRIs are increasingly common in clinical practice. In addition, the use of combined psychotropic medications seems to be on the rise. These trends underscore the importance of discussing and monitoring for drug–drug interactions in clinical practice. SSRIs vary in their potential for such interactions at particular P450 cytochromes. In this way, cimetidine can inhibit CYP2D6 enhancing the therapeutic or adverse effects of CYP2D6 substrates such as fluoxetine or paroxetine. The inverse example is also true, with oculogyric crises and other dystonic reactions occurring after risperidone is added to ongoing treatment with paroxetine. This is understood as being due to paroxetine's inhibition of CYP2D6, a major pathway of risperidone metabolism (59).

Serotonin and Norepinephrine Reuptake Inhibitors

Venlafaxine (Effexor)

Venlafaxine is not FDA approved for the treatment of children and adolescents. Additionally, the evidence for its efficacy is Type V (opinions of respected authorities, based on clinical evidence, descriptive studies, or reports of expert committees: the lowest possible type of evidence). Venlafaxine is an agent that selectively inhibits serotonin reuptake at lower doses (less than 150 mg/day) and inhibits both norepinephrine and serotonin reuptake at doses above 150 mg/day. Meta-analysis of six clinical trials analyzing venlafaxine for MDD in children and adolescents was inconclusive with respect to safety and efficacy, in the context of serious selection and publication bias (60). Venlafaxine is available in 25-, 37.5-, 50-, 75-, and 100-mg tablets, and in 37.5-, 75-, and 150-mg extended release (ER) capsules. Dosing is started with the smallest dose given at bedtime, and with attention to early sedation and dizziness, before moving to a twice-daily regimen. At higher doses (>150 mg/d), venlafaxine can be associated with diastolic hypertension, an effect that is clearly dose dependent in nature, and due to the lack of evidence for efficacy and concerns over safety it should not be recommended in this population

Desvenlafaxine (Pristiq)

Desvenlafaxine is not FDA approved for the use in children or adolescents for any indication. Desvenlafaxine has not been studied in randomized, double-blind, placebo-controlled trials, only in an open-label trial wherein doses between 10 and 100 mg/d in children and 25 to 200 mg/d in adolescents were considered "generally safe and well tolerated" (61). Treatment-emergent adverse effects in the desvenlafaxine group included upper abdominal pain, headache, somnolence, and nausea. In light of the lack of high-quality treatment studies proving a favorable risk–benefit ratio, desvenlafaxine should not be recommended for this population.

Duloxetine (Cymbalta)

Duloxetine is not FDA approved for the use in children or adolescents for any indication. Two recent child and adolescent clinical trials of duloxetine examined fixed doses of duloxetine of 20, 40, and 60 mg against placebo in the treatment of MDD. The trial results were inconclusive while treatment-emergent adverse effects in the duloxetine-treated group included suicidal ideation, with patients receiving duloxetine reported two cases of intentional overdose, nonsuicidal self-injurious behavior, hallucinations, and depression (62). A flexible dose trial had similar findings of inconclusive results, and adverse effects in the duloxetine group including worsening suicidal ideation and suicidal behavior (63). In the context of these results, duloxetine should not be recommended for use in this population.

Tricyclic Antidepressants

Clinical Applications and Empirical Support

TCAs have been used to treat several psychiatric disorders of childhood over the past three decades, including depression, ADHD, OCD, separation anxiety disorder, and enuresis. Although TCAs have been used frequently in clinical practice, evidence for their efficacy in treating children with these psychiatric disorders is inconsistent. For example, a series of carefully conducted controlled trials have consistently failed to show the superiority of any TCA over placebo in the treatment of child- and adolescent-onset depression (64). This poor track record stands in stark contrast to results in adult depression (65). The use of TCAs in non-OCD anxiety is inconclusive. One study found imipramine superior to placebo in the treatment of separation anxiety (66) while another failed to replicate this efficacy (67). Double-blind, placebo-controlled studies have demonstrated the efficacy of desipramine in children with ADHD (68–70). Double-blind, placebo-controlled studies have demonstrated clomipramine to be effective in the treatment of OCD in children and adolescents (3). It is also FDA approved for this treatment in children of 10 years and older. Tricyclic agents continue to have a role in the treatment-refractory ADHD and OCD (Table 6.1.4.2.1). TCAs are considered *third-line* therapy for enuresis, only to be considered if the child has failed alarm therapy and/or desmopressin. In this case, imipramine or desipramine, and in some cases amitriptyline, can be considered.

Mechanism of Action

To varying degrees, all TCAs inhibit the reuptake of norepinephrine and serotonin at presynaptic neurons. Over time, this pharmacologic effect *is presumed* to enhance noradrenergic neurotransmission. Among the TCAs, desipramine is the competitive

antagonist with the highest affinity for the presynaptic norepinephrine receptor. This plays a role in desipramine's efficacy in ADHD and was the impetus for research into other compounds, such as atomoxetine, which also has high affinity for the presynaptic receptors that leads to the inhibition of reuptake of norepinephrine (71). While concerns of a prolonged QTc interval has been demonstrated with desipramine, it appears less likely with atomoxetine. Clomipramine is unique among the TCAs in that it is a more potent inhibitor of serotonin reuptake, which explains its superiority over desipramine in the treatment of OCD.

Tertiary amine TCAs such as imipramine (or amitryptiline, rarely used in psychiatry, but useful in medicine for the treatment of peripheral neuropathy and posttherpetic neuralgia) have highly anticholinergic profiles. Because of this, they are less often used as a first-line intervention, with the exception of enuresis, for which imipramine continues to be used in clinical practice. By contrast, the secondary amine TCAs, desipramine and nortriptyline (derived from their parent compounds, imipramine and amitryptiline, respectively), are less likely to cause orthostatic hypotension, constipation, or urinary retention, and are thus generally preferred in clinical practice.

Pharmacokinetics

Cytochrome P450 2D6 (CYP2D6) is the enzyme responsible for the metabolizing of TCAs. This enzyme demonstrates considerable variation in efficiency and amount between individuals. In this way, patients with greater efficiency or amount of CYP2D6 will metabolize TCAs quickly (termed ultra-rapid metabolizers), while patients with lower efficiency or amount of CYP2D6 will metabolize TCA slowly (termed poor metabolizers). Due to this variation, serum levels of TCAs can show wide variation between different patients even if they are taking the same oral dose. For this reason, therapeutic levels are not well established for TCAs in pediatric populations. Serum levels may be useful, however, to identify children who may be poor metabolizers or ultra-rapid metabolizers, and to rule out toxicity, and assess compliance. A useful metric is that blood levels (ng/mL) of nortriptyline should be close in absolute value to daily oral dosage (mg/day), assuming the patient is neither a poor nor ultra-rapid metabolizer. In this way, 75 mg/day would be expected to yield a steady-state trough level of ~75 ng/mL. When major discrepancies are seen with this pattern, the clinician can further interrogate potential noncompliance, CYP2D6 induction, or ultrafast metabolism (in the case of low levels), or CYP2D6 inhibition, or poor metabolism (in the case of high levels).

Clinical Management

An ECG, pulse, and blood pressure should be obtained prior to starting any of the TCAs. If the patient was taking a monoamine oxidase inhibitor (MAOI), there needs

to be at least a 2-week washout period before initiating treatment with TCAs. A medical and family history that focuses on symptoms associated with syncope, such as dizziness, light headedness, or palpitations in the child, as well as interrogating episodes of syncope or sudden death in first-degree relatives should be completed. Evidence of a normal physical examination (including a full cardiovascular and neurologic assessment) within the past year should also be documented. The typical dose range for TCAs in children is up to 5 mg/kg/day for imipramine, 2.5 mg/kg/day for nortriptyline, and up to 3 mg/kg/day for clomipramine. Imipramine may be started at a dosage of 25 mg and titrated every 4 to 6 days in similar increments to between 100 and 150 mg/day. In younger children, nortriptyline is typically introduced with a 10 mg dose, with titration every 4 to 6 days to a range between 50 and 75 mg/day in divided doses. Clomipramine is usually started at a dose of 25 mg, with gradual titration every 4 to 6 days up to a maximum of 100 mg/day in children younger than 10 years and 3 mg/kg/day or 200 mg (whichever is the smaller dose) in older children. For all of the TCAs, repeat vital signs and ECGs should be obtained, in addition to discussion and investigating potential adverse effects, during the dose adjustment phase and when the maintenance dose has been achieved. As part of the informed consent process, potential cardiac effects and other side effects, as well as reason for repeat ECG monitoring should be discussed with the family and with the child in a manner appropriate for their developmental level. A corrected QT interval (QTc) above 450 ms, a QRS complex longer than 120 ms, or a PR interval greater than 200 ms (72) may warrant dose reduction, or changing to a less cardiotoxic medication, followed by a repeat ECG, if the ECG still shows abnormalities, then reconsider the treatment, and perhaps consider discontinuation. For cases showing clinical benefit and persistent ECG abnormalities, consultation with a pediatric cardiologist is in order.

Adverse Effects

The TCAs have fallen out of favor in pediatric psychiatry due to the increased availability of alternate medications with superior efficacy and tolerability. The TCAs are associated with a range of (largely anticholinergic-based) adverse effects, including sedation, dizziness, dry mouth, excessive sweating, weight gain, urinary retention, tremor, and agitation. In addition to these, TCAs can have dose-dependent adverse effects on cardiac conduction (which can be tracked with an expectable dose-dependent prolongation of the QTc). TCAs also lower the seizure threshold, with clomipramine showing the highest risk. To avoid this, dose and potential drug interactions need to be monitored closely, especially with clomipramine.

For most adverse effects, lowering the dose, changing dose schedules, switching from a tertiary to a secondary amine, or switching out of the TCA class entirely, can often help manage symptoms. For example, to deal with sedation, the medication could be given twice a day, with the higher dosing in the evening. Switching between

TCAs can be helpful at times: For example, imipramine can be changed to nortriptyline in an effort to minimize sedation or constipation. Despite the evidence, of varying quality and reproducibility, showing the efficacy of clomipramine for OCD (FDA approved in children 10 years and older) and desipramine for ADHD (not FDA approved for any indication in childhood), the TCAs appear to be declining in use. This trend is largely due to their side-effect profile and the potential for serious adverse effects, with the rare possibilities of sudden death related to torsade de pointes deteriorating into ventricular fibrillation. Originally reported in cases treated with desipramine, the series of case reports that accrued over ensuing years, and the increased availability of more effective, less dangerous, alternatives has prompted many experts to recommend avoiding TCAs in the pediatric population (73). The selective use of TCAs in nonresponders to first-line agents provides a rational basis for keeping these compounds as potential treatment options, with the following provisos: (1) titration must be stepwise within clear weight-adjusted margins and clearly defined time intervals; (2) careful ECG monitoring must be performed before increasing dose and after reaching maintenance dose; (3) the risk–benefit ratio must be fully disclosed and discussed in the treatment planning process.

Interactions

As with most other psychotropic drugs, the TCAs are metabolized by hepatic enzymes in the cytochrome P450 system (primarily CYP2D6). Several psychotropic (fluoxetine, fluvoxamine, paroxetine), nonpsychotropic drugs (ketoconazole, cimetidine, clarithromycin), and even grapefruit, inhibit the action of one or more of these hepatic enzymes. Inhibition of the enzyme specific for metabolizing the TCA (CYP2D6) can result in toxicity.

Other Antidepressant Medications

Trazodone (Desyrel)

Trazodone is a potent 5-HT2a postsynaptic antagonist and inhibits both serotonin and norepinephrine reuptake. This novel mechanism of action initially raised interest in these compounds, but poor efficacy results in adults, coupled with rare but serious adverse effects (priapism) has led to the selective use of trazodone as an adjunct for insomnia. Trazodone is available in 50-, 100-, 150-, and 300-mg pills, and is prescribed in nighttime dosing for insomnia.

Mirtazapine (Remeron)

Mirtazapine is an alpha-2 adrenoceptor antagonist, which also elicits norepinephrine presynaptic and serotinergic postsynaptic receptor antagonism with a characteristic

side-effect profile, consisting of drowsiness, increased appetite, and weight gain. Mirtazapine is mainly used in anxious and agitated depression with associated sleeping problems, as it has been shown in systematic review to have a positive effect on depressive symptomatology, including insomnia in adults (74). Mirtazapine may be started at 15 mg and titrated slowly to 45 mg in a single dose per day. Pediatric research on this compound is limited.

CHAPTER 6.1.4.3 ■ ANTIPSYCHOTICS

MICHAEL H. BLOCH, CHAD BEYER, LAWRENCE SCAHILL, AND ANDRéS MARTIN

CLINICAL APPLICATIONS AND EMPIRICAL SUPPORT

Antipsychotic agents have become increasingly utilized to treat a variety of mental health conditions in children in recent years including psychosis, bipolar disorder, tic disorders, irritability, and aggression. Although proven efficacious for a number of conditions, antipsychotic use in children is often a difficult treatment decision given the substantial side-effect burden association with these agents. Table 6.1.4.3.1 depicts the current U.S. Food and Drug Administration (FDA)-approved indications for the existing antipsychotics.

Antipsychotics were introduced to adult psychiatry in the early 1950s and began to be used in children shortly thereafter. The antipsychotics can be classified according to chemical family, such as phenothiazines or butyrophenones. Alternatively, they may be classified according to the relative potency of their dopamine blockade. Chlorpromazine and thioridazine are low-potency drugs, in that relatively high doses are required to achieve usual therapeutic effects. By contrast, haloperidol and fluphenazine are high-potency dopamine-blocking drugs. With the introduction of clozapine and a short list of newer compounds, it is becoming commonplace to classify antipsychotics as typical or atypical.

In this section, we will broadly address the variety of FDA-approved and off-label uses that have emerged for antipsychotics in children. More details regarding the dosing of each specific antipsychotic medication will be found in Table 6.1.4.3.1 as well as their approved FDA indications (Table 6.1.4.3.2) and their comparative side effect (Table 6.1.4.3.4). The empirical data supporting the use of each individual antipsychotic medication will be further discussed later in the chapter after the evidence regarding the efficacy of antipsychotic medications as a class are reviewed.

Psychosis

Antipsychotic medications are the first line of treatment for psychosis across the life span. Until the late 1990s, there were very few randomized controlled trials (RCTs) on the treatment of adolescents with psychosis. Most of the treatment guidelines for adolescents with psychosis were derived from data on adults. There is now substantial data demonstrating the efficacy of antipsychotic medications for the treatment of psychosis in children. However, fairly few RCTs of antipsychotic medications exist because of ethical concerns regarding the use of placebo medications in this severely ill population. That being said, the RCTs that do exist

show a strong benefit of antipsychotic medications compared to placebo (1–3). Meta-analysis has not been able to demonstrate a difference in efficacy between different antipsychotic agents for the treatment of pediatric psychosis. Kumar et al. (4) conducted a meta-analysis involving 13 RCTs and a total of 1,112 participants, between 13 and 18 years of age. They found that no convincing evidence that atypical antipsychotics are more effective, at treating the symptoms of psychosis, than typical antipsychotics (4). Given the lack of differences in efficacy between different antipsychotic agents, choice of medication should be primarily made based on the quality of available data as well as the side-effect profile of these medications in combination with patient preference.

Abbreviations: B, severe behavioral problems marked by combativeness and/or explosive behavior and short-term treatment of hyperactive children who show excessive motor activity with accompanying conduct disorders; D, acute depressive episodes associated with bipolar I disorder (along with fluoxetine); H, hyperactivity; I, irritability associated with autism disorder; M, manic or mixed episodes associated with bipolar I disorder; P, psychosis; S, schizophrenia; T, Tourette syndrome.

TABLE 6.1.4.3.2

CLINICAL GUIDANCE FOR ANTIPSYCHOTIC MEDICATIONS UTILIZED IN PEDIATRIC PRACTICE

	Pediatric			Adult		
	Starting Dose (mg/day)	Typical Dose Range (mg/day)	Number of Daily Doses	Starting Dose (mg/day)	Typical Dose Range (mg/day)	Number of Daily Doses
Second-Generation (Atypical) Antipsychotics						
Risperidone	0.5–2	1–6	1–2	2	2–6	1–2
Aripiprazole	2–5	5–30	1	5–15	10–30	1
Quetiapine	25–50	100–800	2–3	50–100	150–800	2–3

Olanzapine	2.5–5	5–20	1	5–10	5–20	1
Ziprasidone	5–20	40–160	2	40–80	80–160	2
Clozapine	12.5–50	300–900	2	25–50	300–900	1–2
Paliperidone	3	3–12	1	3–6	3–12	1
Lurasidone	20	20–160	1	20–40	20–160	1
Asenapine	5	5–20	2	10–20	10–20	2
First-Generation (Typical) Antipsychotics						
Haloperidol	1–10	2–30	2–3	2–15	2–50	2–3
Molindone	25–75	50–225	3–4	50–75	50–225	3–4
Pimozide	0.5–2	1–6	1–2	1–2	2–10	1–2
Chlorpromazine	30–75	50–200	4	30–75	200–400	3–4
Perphenazine	6–12	12–32	2–4	12–24	16–32	2–4
Fluphenazine	1–10	2.5–20	3–4	2–10	10–40	3–4
Thioridazine	25–50	25–200	2–4	150–300	200–800	2–4

Further supporting the absence of evidence in a difference in efficacy between antipsychotic agents for schizophrenia came from the Treatment of Early-Onset Schizophrenia Study (TEOSS) (5). TEOSS was a double-blind multisite trial which randomly assigned pediatric patients (8 to 19 years) with schizophrenia and schizoaffective disorder to treatment with either olanzapine (2.5 to 20 mg/day), risperidone (0.5 to 6 mg/day), or molindone (10 to 140 mg/day, plus 1 mg/day of benztropine) for 8 weeks. TEOSS demonstrated no difference in the primary efficacy measure between the three antipsychotic medications. However, the atypical antipsychotics, especially olanzapine, were associated with significantly greater gain. The magnitude of weight gain with olanzapine (6.1 kg over the 8-week trial) was so significant that the olanzapine arm was discontinued early for safety reasons (5).

Bipolar Disorder

Multiple randomized, placebo-controlled trials have demonstrated that atypical antipsychotics are more effective than placebo for children with bipolar disorder experiencing manic or mixed episodes. Furthermore, a large, multicenter, NIH-funded, head-to-head trial comparing an atypical antipsychotic, risperidone, with two mood stabilizers (lithium and valproic acid) demonstrated the superiority of risperidone over these two mood stabilizers for the treatment of manic symptoms in pediatric bipolar disorder (6). An earlier smaller trial comparing risperidone to valproic acid similarly found greater improvement in the risperidone group although not to the degree of statistical significance. Similarly, these results were reconfirmed when risperidone was demonstrated to be superior to valproic acid for the treatment of manic symptoms in younger children aged 3 to 7 years (7). After the findings from these two important clinical trials antipsychotic medications have become the initial

treatment of choice for pediatric mania often in conjunction with mood stabilizers in severe cases.

Tic Disorders

Meta-analysis of RCTs of antipsychotic agents has suggested that they are likely the most effective pharmacologic intervention currently available to treat children with tic disorders (8). Specifically, meta-analysis of five randomized, placebo-controlled trials involving 167 participants demonstrated that antipsychotics had a modest effect size (ES = 0.58) in reducing tic symptoms. Both stratified subgroup analysis and head-to-head trials failed to demonstrate a difference in efficacy between antipsychotic agents. Haloperidol, risperidone, aripiprazole, and pimozide have specific evidence of efficacy compared to placebo for the treatment of tics (9).

Irritability and Aggression

RCTs of atypical antipsychotics have demonstrated a benefit compared to placebo for irritability and aggression in children with and without ASD (10,11). In these RCTs, atypical antipsychotic treatment has been shown to be effective as monotherapy or as an adjunct to evidence-based behavioral treatment. Risperidone and aripiprazole have been the primary atypical antipsychotics examined for the treatment of aggression and irritability in pediatric populations.

Treatment-Refractory Obsessive–Compulsive Disorder

There exist no randomized, placebo-controlled trials of antipsychotics for treatment-refractory obsessive–compulsive disorder (OCD) in pediatric populations. However, antipsychotic augmentation remains an available treatment option for children with severe OCD that has not improved sufficiently on selective serotonin reuptake inhibitor (SSRI) pharmacotherapy and cognitive behavioral therapy. Meta-analysis of nine RCTs involving 278 participants demonstrated a significant benefit (absolute risk difference (ARD) in favor of antipsychotic augmentation of 0.22 [95% confidence interval (CI): 0.13 to 0.31]) compared to placebo. The subgroup of OCD patients with comorbid tics appears to have a particularly beneficial response to antipsychotic augmentation, ARD = 0.43 (95% CI: 0.19, 0.68) (12). Meta-analysis also demonstrated no significant differences in efficacy between individual antipsychotic agents. Based on the currently available data, antipsychotic augmentation should only be attempted following a treatment failure of 10 to 12 weeks of SSRI pharmacotherapy of adequate dose and duration (13). Further, antipsychotic treatment should be discontinued if there is no treatment improvement within 6 to 12 weeks of treatment.

Treatment-Refractory Depressive Disorders

Similar to OCD, there exists no randomized, placebo-controlled trials examining the efficacy of antipsychotic augmentation in treatment-refractory depression. Meta-analysis has demonstrated the efficacy of atypical antipsychotics as an augmentation strategy for treatment-refractory major depression and persistent depressive disorder in adults. Meta-analysis of 16 randomized, placebo-controlled trials with 3,480 subjects demonstrated that adjunctive atypical antipsychotics were significantly more effective than placebo (response: odds ratio = 1.69, 95% CI: 1.46 to 1.95) (14). Meta-analysis also demonstrated no evidence of difference in efficacy between antipsychotics studied. Antipsychotics should be used with extreme caution in children with major depression (even as compared to OCD) as there exists a larger number of potential therapeutic options beyond SSRIs with evidence of efficacy in adults. These alternative pharmacologic options have a lower side-effect burden than antipsychotics.

Atypical Antipsychotics

The dosing recommendations for each individual antidepressant medication is depicted in Table 6.1.4.3.2. Antipsychotics commonly used in pediatric populations are also discussed individually in the following section. The relative side-effect profiles of different antipsychotic agents are also depicted in Table 6.1.4.3.3.

Risperidone (Risperdal)

Large multisite studies in adults with schizophrenia have shown that risperidone is an effective antipsychotic with lower risk of neurologic side effects compared to traditional antipsychotics such as haloperidol (15). Unlike clozapine, it is associated with an increase in prolactin suggesting more potent D_2 blockade. At doses above 6 mg/day, the risk of neurologic side effects increasesin a dose-dependent manner. This apparent dose-threshold effect may be due to protective effects of 5HT2 receptors to which the atypical antipsychotics (AAPs) appear to bind preferentially. In this model, as the dose of the antipsychotic medication increases, 5HT2 receptors become saturated, which is followed by an increase in D_2 binding (16). Alternatively, the protective role of 5HT2 may be less important than D_2 occupancy. Occupancy is influenced by rate of association (binding to the receptor) and the rate of dissociation (release from the receptor). As pointed out by Kapur and Seeman (17), AAPs have lower affinity to D2 receptors because they are more easily displaced by endogenous dopamine. The result of this “fast off” property of the AAPs is that at usual doses these drugs remain under the D_2 occupancy threshold that is associated with neurological side effects. For example, 65% D2 occupancy is the

estimated threshold for antipsychotic activity compared to 80% occupancy for neurologic side effects (17). At usual doses, risperidone and olanzapine do not exceed the 80% threshold, but haloperidol does (17).

TABLE 6.1.4.3.3

SIDE EFFECT PROFILE OF COMMONLY PRESCRIBED ANTIPSYCHOTIC MEDICATIONS

	Extrapyramidal	Sedation	Weight Gain		Hyperglycemia	Anticholinergi
Second-Generation (Atypical) Antipsychotics

Thioridazine	+	++	+		+	++

Key: + ≥20% incidence; **10–20% incidence, *1–10% incidence; –minimal evidence of effect.

Risperidone is the best studied AAP in pediatric populations. An emerging body of evidence from short-term, placebo-controlled, randomized clinical trials shows that risperidone is safe and effective for serious behavioral problems in children with autism (18,19); severe disruptive behavior (20–23); and Tourette syndrome (TS) (23,24). A few studies have also shown that short-term gains endure over the intermediate term (23,25).

Risperidone (1 to 3 and 4 to 6 mg/day) has been demonstrated to be more effective than placebo in a 12-week RCT of 160 adolescents schizophrenia (2). Interestingly, there was no evidence of a difference in efficacy between the low (1 to 3 mg) and high (4 to 6 mg) dosing strategies for risperidone (2). The TEOSS study examined olanzapine, risperidone, or molindone; found that only 12% of youths with early-onset schizophrenia spectrum disorders continued on their originally

randomized treatment at 52 weeks (26). Risperidone showed significantly greater weight gain than molindone but less than olanzapine.

Risperidone has been shown effective at daily doses of 0.5 to 2.5 and 3 to 6 mg for the treatment of acute mania in adolescents with bipolar disorder (27). Consistent with the trials of adolescent schizophrenia, higher doses of risperidone showed no greater efficacy in treating acute mania but were associated with a worse side-effect profile, while the 0.5 to 2.5 mg exhibited a better side-effect profile (27). The Treatment of Early Age Mania (TEAM) trial demonstrated that risperidone was more efficacious than lithium and divalproex sodium for the initial treatment of childhood mania but had potentially serious metabolic effects, including an increased risk for weight gain, increased BMI, and increased prolactin levels. A smaller trial in preschool children with manic symptoms demonstrated a benefit of risperidone compared to both placebo and valproic acid (7).

Risperidone has been shown to be more effective than haloperidol in the treatment of behavioral symptoms, impulsivity, language skills, and impaired social relations in children with ASD (28). The Research Unit in Pediatric Psychopharmacology Autism Network completed an 8-week, placebo-controlled study of risperidone in 101 children with autism accompanied by tantrums, aggression, and self-injury (18). At an average dose of 1.8 mg/day, the risperidone group improved 57% on a parent-rated scale measuring the target symptoms of tantrums, aggression, and self-injury compared to 14% in placebo. Similarly, blinded clinicians rated 75% of children in the risperidone group as much improved or very much improved compared to 12% for the placebo group. Children initially randomized to placebo who showed no improvement were offered treatment in an 8-week open-label trial using the same dosing schedule that was used in the double-blind trial. Sixty-three who showed a positive response to risperidone (in the double-blind or the open-label trial) were followed forward for an additional 4 months to evaluate the stability of gains and continued safety (25). Finally, at the 6-month mark, children were randomly assigned to remain on risperidone or to gradual withdrawal from active medication by placebo substitution over a 4-week period. This study showed that the short-term gains of risperidone were stable over time and that it was not necessary to increase the dose of medication to maintain the observed benefits. Thirty-two children entered the double-blind, placebo-controlled discontinuation phase. Ten of 16 children assigned to discontinuation showed a return of symptoms compared to two of 16 children who remained on risperidone who met prespecified criteria for relapse.

Aman et al. (20) conducted a 6-week, randomized, placebo-controlled risperidone trial in 118 children with disruptive behavior. The subjects ranged in age from 5 to 12 years; many were functioning in the intellectually disabled range (IQ 36 to 84). After 6 weeks of risperidone, the active treatment group showed nearly a 16-point improvement on the parent-rated Nisonger Child Behavior Rating Form compared to a 6-point improvement in the placebo group. The average dose of

risperidone was 1.16 mg/day. This finding was replicated in a separate trial using an identical design and similar inclusion criteria (23). Both studies included a 12-month extension phase, which showed that gains were stable (23). There is also emerging data to suggest risperidone may be an effective treatment for irritability in children without ASD. An RCT of risperidone in children with severe aggression related to ADHD demonstrated that risperidone had added benefit when added to a combination of parent training and stimulant treatment (29).

In a placebo-controlled study of risperidone that included both children and adults, risperidone was superior to placebo for the treatment of tics in Tourette syndrome (24). Thirty-four subjects (26 children and 8 adults) were randomly assigned to placebo or risperidone. After 8 weeks of treatment with doses ranging from 1 to 2 mg/day in the pediatric sample, risperidone was associated with a 36% improvement on a clinician-rated measure of tic severity, which was significantly better than the 9% in the placebo group ($p < 0.01$). No neurologic side effects were observed in this study. Weight gain averaged 2.8 kg in the active treatment group compared to 0.7 kg in the placebo group ($p < 0.05$). Treatment-emergent social phobia was observed in two cases in the risperidone group, which has been reported by others (30).

Risperidone has also been compared to pimozide in a randomized, double-blind trial (31). In that study, risperidone and pimozide were similar in their positive effects, with reductions in tic severity of 44% and 47%, respectively. Not surprisingly, the pimozide group reported more neurologic side effects. Weight gain was greater in the risperidone group (4.5 kg compared to 2.7 kg). Dose ranges were similar, up to 6 mg/day for each drug. The study included 50 subjects in total, but only 17 were in the pediatric age group. Results in the pediatric sample were not reported.

In many of these studies, the drug was initiated at 0.5 mg/day (0.25 in younger children) and increased by 0.5 mg every 5 to 7 days to a range of 1 to 2.5 mg/day in a single dose or two divided doses. Studies by Aman et al. (20), Snyder et al. (23), and Findling et al. (22) used single-daily dosing. Not surprisingly, the average dose in these studies was lower than the studies that used a twice-daily dosing schedule. Taken together, these data suggest that twice-a-day dosing may be better tolerated, though single-day dosing may be considered if the total daily dose is low (less than 1.5 mg/day).

Aripiprazole (Abilify)

Aripiprazole is a third-generation antipsychotic due to its novel mechanism of action. Aripiprazole is classified as a partial dopamine agonist. This term refers to the fact that aripiprazole binds with presynaptic dopamine receptors, which is purported to turn down the dopamine system in brain regions with increased dopaminergic tone. In addition, like the other AAPs, aripiprazole has serotonin-blocking properties at the

five HT2 receptor sites. Aripiprazole has been evaluated in pediatric populations for many of the same target symptoms described earlier for risperidone.

Aripiprazole at doses of 10 and 30 mg/day has been demonstrated to be superior to placebo for the treatment of adolescents with schizophrenia (1). Symptom improvement and remission rates were higher (but not statistically significantly so) in the 30 mg compared to the 10-mg aripiprazole group. Similarly, aripiprazole has been demonstrated to be effective compared to placebo for the treatment of acute mania or maintenance treatment for adolescent bipolar disorder (32). Similar to its benefits in adolescent psychosis, aripiprazole demonstrated efficacy for acute bipolar manic and mixed episodes in adolescence with greater (though again not statistically significant benefits observed in the 30-mg treatment arm compared to the 10-mg treatment arm (33)). For maintenance treatment of adolescents with bipolar disorder started on aripiprazole, subjects randomized to aripiprazole had a longer time to the their next mood episode and lower likelihood of medication discontinuation than subjects randomly assigned to placebo (32). In comparison with placebo, aripiprazole showed greater efficacy, was well tolerated, and safe in the short-term treatment of children and adolescents with Tourette's disorder (34). Several placebo-controlled trials have demonstrated the superiority of aripiprazole for the treatment of irritability in children with ASD (35,36). In a double-blind, randomized, placebo-controlled, parallel-group study, 218 children (6 to 17 years) with irritability and aggression symptoms were randomized to aripiprazole (5, 10, or 15 mg/day) or placebo for 8 weeks. All doses of aripiprazole were more effective than placebo with a clear dose–response pattern (36). Aripiprazole and risperidone are the only FDA-approved medications for treating irritability in autistic disorder, a head-to-head study, demonstrated that aripiprazole as well as risperidone lowered aberrant behavior checklist scores during 2 months, and that while the safety and efficacy of aripiprazole (mean dose 5.5 mg/day) and risperidone (mean dose 1.12 mg/day) were comparable, the rates of adverse effects were not significantly different between the two groups (37).

Quetiapine (Seroquel)

Quetiapine is a second-generation antipsychotic that is gradually being shown to be effective and safe for treatment or augmentation in a variety of pediatric conditions. In a 6-week study of adolescent patients, doses of 400 and 800 mg/day provided significant improvements in symptoms associated with schizophrenia in adolescent patients (primarily the Positive and Negative Syndrome Scale total score change) (3). Quetiapine was generally well tolerated with a profile broadly similar to that reported in adult and adolescent populations (3). A head-to-head study of quetiapine and risperidone was conducted into the treatment of the often comorbid bipolar II and conduct disorder (3,38). Both treatments showed similar efficacy in reducing manic symptoms and aggression. In BD type II, CD comorbidity, quetiapine, and

monotherapy may be effective and relatively safe (38). Quetiapine demonstrated efficacy in reducing manic symptoms of bipolar disorder in a large, placebo-controlled trial of bipolar mania (39) but not for bipolar depression (40).

Ziprasidone (Geodon)

This atypical antipsychotic medication has also been shown to be effective in adults with schizophrenia (41). Like risperidone, it is a potent blocker at the D_2 and 5-HT_2 sites. Compared to risperidone, however, much larger doses are required to achieve an antipsychotic effect. For example, the usual dose of risperidone in adults with schizophrenia is 6 mg/day. By contrast, the dose of ziprasidone is typically in the range of 40 to 160 mg/day or higher, given in two divided doses (42). In the first trial, 28 children (age 7 to 17 years) with TS or chronic motor tic disorder were randomly assigned to placebo ($N = 12$) or ziprasidone ($N = 16$) under double-blind conditions. The mean dose of ziprasidone was approximately 30 mg/day given in divided doses. Using the same outcome measure mentioned for the risperidone study in TS, ziprasidone was associated with a 35% improvement in tic severity, compared to a 7% decline in the placebo group ($p < 0.05$) (43). Common side effects included moderate sedation (one subject), mild sedation (11 subjects), insomnia (four subjects), and akathisia (one subject). There were no changes in laboratory values, cardiac conduction times, or body weight in the ziprasidone group. Although we now know that ziprasidone is associated with greater QTc prolongation compared to other atypical antipsychotic agents.

While generally well tolerated, with an overall neutral weight and metabolic profile, ziprasidone failed to separate from placebo in a 6-week randomized, placebo-controlled trial in 283 adolescents with schizophrenia (44). By contrast, a 4-week, randomized, double-blind, placebo-controlled multicenter trial examining the efficacy of ziprasidone in 237 adolescents with bipolar disorder demonstrated significant benefit compared to placebo for manic symptoms (45).

Olanzapine (Zyprexa)

Olanzapine is another agent with atypical features that are preserved only in the lower dose range (<20 mg/day in adults). In a randomized, double-blind, placebo-controlled trial, olanzapine was superior to placebo, and has been approved by the FDA for the acute treatment of bipolar I depression in patients 10 to 17 years of age. Benefits should be weighed against the risk of adverse events, particularly weight gain and hyperlipidemia (46). While olanzapine was as effective as other antipsychotics in the TEOSS study, the olanzapine treatment arm was terminated early due to concerns about excessive weight gain (47). This weight gain was an average of 6.1 kg in 8 weeks in the olanzapine arm. Because of the excessive weight gain associated with olanzapine, olanzapine is generally not recommended unless

children have failed other antipsychotic medications.

Asenapine (Saphris)

Asenapine is an atypical antipsychotic given in sublingual formulations that has FDA approval for the treatment of schizophrenia and acute manic or mixed episodes of bipolar disorder in adults. Asenapine was recently FDA approved for the treatment of adolescents (ages 10 to 17 years) experiencing acute manic or mixed episodes of bipolar disorder. This approval was based on a 3-week randomized, placebo-controlled trial of adolescents with bipolar disorder I (48). All three doses of asenapine (2.5, 5, and 10 mg bid) showed benefit compared to placebo on reducing manic symptoms on the Young Mania Rating Scale. Side effects associated with asenapine treatment included somnolence, sedation, oral numbness, and increased appetite/weight gain. Asenapine is noted to have less anticholinergic and cardiovascular side effects than many other available antipsychotics and its sublingual formulations may be of use in younger children with difficulty swallowing pills (although such use in younger children is off-label and has not supported with adequate research).

Clozapine (Clozaril)

Clozapine was the first AAP agent to be developed and entered into the marketplace. It is a dibenzodiazepine derivative and chemically unrelated to any of the typical antipsychotic drugs. Soon after it was introduced in 1960, its effectiveness in treatment-resistant patients with schizophrenia was recognized, but initial enthusiasm waned following the report of fatal agranulocytosis in a series of cases in Europe. Two open studies (49,50) and one controlled comparison with haloperidol (51) have been carried out in pediatric populations. Collectively, these studies included 53 patients from ages 6 to 18 years. Clozapine was effective in 30 of 53 (56%) of these patients. This figure is impressive considering that this was a group of treatment-resistant patients. In the controlled trial, doses ranged from 125 to 525 mg/day given in divided doses. Although there were no reports of extrapyramidal symptom (EPS), several serious adverse effects were observed, most notably seizures ($N = 1$) and hematopoietic abnormalities ($N = 4$). Weight gain was a frequently observed complication of clozapine treatment. Due to differences in the duration of the studies, however, it is not possible to aggregate data across them. Additional longitudinal studies of clozapine use in children have continued to suggest a promising short-term and longer-term response. However, these studies also suggest that the rates of neutropenia may be higher in children treated with clozapine compared to adults (52).

Typical Antipsychotics (Antipsychotics)

Chlorpromazine (Thorazine)

Chlorpromazine is an aliphatic agent, and was the first antipsychotic used in children with severe behavioral disturbances. With the introduction of newer agents, the use of chlorpromazine has declined, although it is still routinely used for the acute management of agitation or aggression, where it can be administered through either oral or intramuscular (IM) routes. When used IM, careful caution must be paid to vital signs, as significant hypotension can occur even at seemingly low doses (e.g., <25 mg).

Molindone (Moban)

Molindone is a first-generation antipsychotic over which, second-generation antipsychotics have not proven efficacy. Molindone was the typical antipsychotic comparator in the TEOSS trial (5). No significant differences were found among treatment groups in response rates although molindone had the highest absolute response rate (molindone: 50%; olanzapine: 34%; risperidone: 46%) and magnitude of symptom reduction (53). Molindone was associated with a significantly higher rate of akathisia and lower amount of weight gain compared to olanzapine and risperidone.

Haloperidol (Haldol)

A butyrophenone that is structurally unrelated to the phenothiazines represents the prototype of a high-potency typical antipsychotic. Since its introduction in the early 1960s, it has been used to treat children with psychosis, aggressive behavior, tics, and behavioral dyscontrol associated with autism (54,55).

Compared to the low-potency antipsychotics, haloperidol is much more likely to cause EPS, but it is less sedating. The dose of haloperidol varies according to the target symptoms. For example, in school-age children with tics or severe behavioral dyscontrol associated with autism, the dose is typically in the range of 0.75 to 2.5 mg/day (43,56). By contrast, doses in the range of 10 mg/day may be used to deal with an acute psychotic episode (57).

Fluphenazine (Prolixin)

Fluphenazine, a piperazine phenothiazine, is not approved for children under the age of 12 years, and has not been well studied in pediatric populations. At low dosages (0.04 mg/kg/day), fluphenazine decreased aggression, hyperactivity, and stereotypies in an open-label study of 12 children with PDD (58). At a mean dose of 7 mg/day in divided doses (range, 2 to 15 mg/day), fluphenazine reduced tics and was favored over haloperidol by most patients (59). This open-label trial of 21 patients with TS

included both children and adults, but results were not separately reported by age group.

Thiothixene (Navane)

A thioxanthene derivative, this mid-potency agent is structurally unrelated to the phenothiazines or the butyrophenones. It is approved for the treatment of psychosis in children over the age of 12 years. The available evidence in children under age 12 indicates that thiothixene is less sedating than low-potency antipsychotics, and that it may have a lower risk of EPS than high-potency antipsychotics such as haloperidol (60).

Pimozide (Orap)

A diphenylbutylpiperidine, pimozide it is not related to the phenothiazines or to haloperidol. It is a potent blocker of dopamine at the D_2 postsynaptic receptors, and it is used to treat tics in TS. In placebo-controlled studies involving both children and adults, pimozide has been shown to be superior to placebo in reducing tics (61). It has also been evaluated in head-to-head trials with haloperidol. These studies suggest that pimozide is equivalent to haloperidol with respect to tic suppression, and that it has a more favorable side-effect profile (55,62).

Mechanism of Action. The principal therapeutic action of the traditional antipsychotics is to block postsynaptic D2 receptors (17). The observed differences across traditional antipsychotics may be related to the regional specificity of the D_2 blockade (striatum vs. limbic structures), and the effects on other neurotransmitter systems. By contrast, the atypical antipsychotics block both dopamine and serotonin postsynaptic receptors to varying degrees. The addition of postsynaptic 5-HT blockade may lower the risk of neurologic side effects and perhaps of tardive dyskinesia (TD) as well. As noted previously, the protective role of 5HT2 may be less important than D_2 occupancy. Occupancy is influenced by rate of association (binding to the receptor) and the rate of dissociation (release from the receptor). Because the AAPs are more easily displaced by endogenous dopamine, the occupancy at D_2 receptors is lower than the traditional antipsychotics of similar potency. The result of this "fast-off" property of the AAPs is that at usual doses these drugs remain under the D_2 occupancy threshold and less likely to produce neurologic side effects.

Antipsychotic medications may also have anticholinergic and antihistamine effects, as well as adrenergic-blocking effects. These additional pharmacologic properties probably do not contribute to the therapeutic effects of the antipsychotic drugs, but do have an impact on side-effect profiles. For example, low-potency antipsychotics such as chlorpromazine and thioridazine cause more sedation, dry

mouth, and constipation, presumably due to antihistamine and anticholinergic effects. Their propensity to cause hypotension may be related to alpha-adrenergic blockade.

Adverse Effects. Neurologic side effects such as dystonic reactions, rigidity, and akathisia are more common with the high-potency antipsychotics. In addition to these neurologic side effects, adverse effects of the typical antipsychotic drugs in children and adolescents can include weight gain, increased risk of diabetes, elevated prolactin levels with possible emergence of gynecomastia in boys, and galactorrhea or amenorrhea in girls. Drowsiness is a common side effect with the low-potency antipsychotic agents, but may occur in the high-potency antipsychotics as well. Anticholinergic side effects such as dry mouth, constipation, and blurred vision should also be monitored. As noted, thioridazine, pimozide, ziprasidone, and other antipsychotics can prolong cardiac conduction times (63). Recommendations on whether to obtain ECGs at baseline and how often to monitor cardiac conduction times when using antipsychotics in children and adolescents are not consistent. For example, electrocardiograms at baseline and during maintenance treatment with antipsychotics are recommended in one guideline (64) but not in others (65). The explanation for this inconsistency is not clear, but may simply reflect the incomplete state of current evidence. Thioridazine has largely fallen out of use. Expert opinion in published guidelines for the use of antipsychotics in TS indicates that when using pimozide or ziprasidone in children and adolescents, an ECG should be obtained prior to treatment, during the dose adjustment phase and periodically thereafter (66). One important difference in considering treatment with pimozide or ziprasidone is their relative vulnerability to drug–drug interaction. Pimozide is a substrate for the CYP 3A4 pathway and will show a dramatic rise in serum level following the addition of a potent 3A4 inhibitor such as erythromycin. Case reports indicate that this type of interaction may have serious consequences (67). Ziprasidone, on the other hand, does not appear to be vulnerable to drug–drug interaction due to its use of multiple metabolic pathways (68).

TABLE 6.1.4.3.4

MONITORING RECOMMENDATIONS FOR USE OF ANTIPSYCHOTIC MEDICATIONS IN PEDIATRIC AND ADULT PATIENTS

	Baseline	4 Wks	8 Wks	12 Wks	Annually	Reassess
Weight (BMI)	X	X		X	X	3 mo
Waist Circumference	X				X	Annually
Blood Pressure	X			X	X	3 mo for 1 yr, then annually
Fasting Glucose	X		X		X	3 mo for 1 yr, then annually
Fasting lipid profile	X			X	X	Annually

Although the atypical antipsychotics are less likely to cause neurologic side effects, they are not free of adverse effects. Clozapine is associated with a low risk

of agranulocytosis and toxic megacolon. For this reason, it is only used in treatment-resistant schizophrenia.

Other adverse effects of clozapine include lowered seizure threshold and tachycardia. An adverse effect of the AAPs that has emerged as a clinically important concern is increased appetite and weight gain. Several reports in pediatric samples across several diagnostic groups have shown that clozapine, olanzapine, quetiapine, and risperidone are associated with excessive weight gain (18,20,24,51,69–72). The weight gain associated with olanzapine reported in two trials ranged from 4 to 6 kg over 6 to 12 weeks' duration (70,73). Table 6.1.4.3.3 depicts the relative risk of weight gain between antipsychotic agents. Generally, aripiprazole and ziprasidone are considered relatively weight neutral but still associated with some weight gain with olanzapine and clozapine causing a large risk of weight gain. Table 6.1.4.3.4 depicts the currently recommended monitoring parameters for antipsychotic medications in pediatric populations. Longitudinal studies examining the trajectory of weight gain with AAP treatment in children and adolescents suggest that the rate of weight gain is greatest in the first 2 months of treatment, with some leveling thereafter. The health consequences of obesity can be significant, including increased serum cholesterol, triglycerides, and drug-induced type II diabetes (74).

The risk of TD increases as a function of dose and duration, but it may occur with brief exposures as well. TD has been reported in pediatric patients (75). Thus, children and adolescents treated with antipsychotics should be monitored for abnormal movements. The largest systematic study to date (76) raises questions regarding the difficulty in distinguishing between TD and withdrawal dyskinesia (77). In that study, 30% of children between the ages of 2 and 8 years showed persistent dyskinetic movements for up to 3 months of follow-up after a planned withdrawal from haloperidol.

Questions of how and when to discontinue antipsychotic medication are critical ones, but data to guide clinical decisions are limited. To minimize TD, dose reductions should be done gradually while evaluating changes in symptom severity. In autism and tic disorders, discontinuation may be considered annually for cases in which good control has been achieved. If symptoms persist, the maintenance dose of the antipsychotic should be reduced to the lowest possible one sufficient to maintain symptomatic control and minimize overall exposure (78). Based on the collective experience with clozapine, the newer atypicals may also have a lower risk of TD. More study, such as long-term follow-up of clinical samples treated with atypical antipsychotics and careful postmarketing surveillance of these agents in pediatric populations, is needed.

Neuroleptic malignant syndrome (NMS) is a rare adverse effect due to antipsychotic medications. NMS is characterized by high fever, autonomic instability, and muscle breakdown (reflected by elevated CPK titers) and is potentially life threatening. The mortality rate may be as high as 9% in children and adolescents

(79). Discontinuation of the medication is usually all that is required, highlighting the importance of early identification of the condition. In severe cases, IV fluids are needed, and some authors have advocated the use of dantrolene or bromocriptine to hasten recovery.

Treatment of Antipsychotic-Associated Adverse Effects: Emphasis on Anticholinergic Agents

Among the many potential side effects associated with the traditional antipsychotics, neurologic side effects represent some of the most common and ones likely to be treated with additional pharmacotherapy. Acute neurologic side effects include dystonia, torticollis, or oculogyric crisis. Chronic side effects include parkinsonism, tremor, rigidity, mask-like faces, or festinant gait. These adverse effects can be prevented or reversed with the judicious use of anticholinergic agents. Given that all of these adverse effects are associated with unchecked D_2 receptor blockade, it follows that they are most common with high-potency traditional agents (such as haloperidol or fluphenazine) and least common with low-potency compounds (such as chlorpromazine). Although less common with atypical antipsychotics, the risk of neurologic side effects increases at higher dose levels of risperidone, olanzapine, or ziprasidone. In most instances, the anticholinergics discussed here are used in combination with high-potency agents, and they should rarely (if at all) be used in combination with lower-potency drugs. Not only are the low-potency agents less likely to cause neurologic side effects, the addition of anti-parkinsonian mediations may exacerbate the inherent anticholinergic properties of low-potency antipsychotics. This point is of more than academic interest: The additive effects of combining agents with anticholinergic or anti-histaminergic effects can rapidly lead to behavioral toxicity, including paradoxical agitation, confusion, or full-blown delirium.

The two most commonly used agents in this category are diphenhydramine (Benadryl) and benztropine (Cogentin). The antihistamine diphenhydramine is best used in acute situations, both given its ready availability (in household medicine cabinets and crash carts alike), as well given its side-effect profile. However, the sedation induced by diphenhydramine can be intense, so this agent should be used sparingly as a maintenance intervention. Alternatively, such sedation can be exploited therapeutically in the acutely agitated patient. By contrast, the purely anticholinergic compound benztropine is preferred for longer-term management of neurologic side effects, as it does not induce somnolence. Diphenhydramine is usually dosed in the 12.5 to 50 mg range (single or repeat dose, administered orally or by IM injection), while benztropine is used in 0.5-, 1-, or 2-mg doses, usually given orally in a bid regimen. The long-term use (>1 month) of anticholinergic agents should be avoided if at all possible, particularly in younger children, for whom the

resulting Sjögren-like iatrogenic syndrome can lead to widespread cavities. The slow upward adjustment of antipsychotics, coupled with time-limited (as opposed to regular) use of these agents, can avert unnecessary longer-term use.

CHAPTER 6.1.4.4 ■ MOOD STABILIZERS

MICHAEL H. BLOCH, CHAD BEYER, LAWRENCE SCAHILL, AND ANDRÉS MARTIN

MOOD STABILIZERS

The prototype for the chemically unrelated group of mood stabilizers is lithium, which has been used in the treatment of bipolar illness for over 50 years. It is the only mood stabilizer with two FDA-approved indications for acute mania and maintenance therapy of bipolar disorder in youth (older than 12 years). Other mood stabilizers include valproate (VPA), carbamazepine (CBZ), lamotrigine, oxcarbazepine (OXC), and topiramate. Of these, only VPA, CBZ, and lamotrigine have been carefully studied in adults. The anticonvulsants, CBZ, and VPA have been FDA approved for the treatment of acute mania in adults with bipolar disorder but currently have no FDA indication in children. Lamotrigine only has FDA approval for maintenance treatment of bipolar disorder in adults. In addition to bipolar-spectrum conditions, the mood stabilizers are commonly used in pediatric psychopharmacology for the management of aggressive outbursts and intense emotional lability. Although the empirical database for these indications (including bipolar disorders) is modest, Table 6.1.4.4.1 depicts the varying characteristics, indications, and dosing recommendations for mood stabilizers with evidence of efficacy in pediatric populations.

As discussed in an earlier section of this chapter, several atypical antipsychotics have demonstrated efficacy and approval for treatment of mania and mixed episodes as well as maintenance treatment in pediatric bipolar disorder. A multicenter, randomized clinical trial comparing the efficacy of risperidone to valproic acid and lithium for the treatment of children and adolescents with acute mania has dramatically shifted the evidence base away from mood stabilizers in recent years. The Treatment of Early Age Mania (TEAM) trial demonstrated that risperidone was superior to lithium and divalproex sodium for the initial treatment of childhood mania in terms of both likelihood of response and overall symptoms of mania. The response rate for acute mania was significantly higher with risperidone (65%) than with lithium (36%) or valproic acid (24%) (1). Similarly, a smaller trial in preschool children 3 to 7 years old with manic symptoms of bipolar disorder further demonstrated a benefit of risperidone compared to both placebo and valproic acid in younger children (2). After the results of these two informative trials, the use of mood stabilizers in bipolar disorder is generally reserved for simultaneous treatment with atypical antipsychotics for acute mania or mixed episodes or as the treatment for bipolar depression (or maintenance treatment).

Complicating the evidence surrounding the treatment of pediatric bipolar disorder is the relative controversies surrounding the diagnostic criteria for pediatric

populations in recent years. The inconsistent diagnoses and treatment of those with bipolar disorder that are handed down to children often change the patient's view of themselves irrevocably. The prevalence of childhood bipolar disorder has shown a steep increase (40 × increase over the past 10 years) (3). Recent research suggests that episodic versus persistent irritability justifies two distinct disorders, with the latter more suited to a diagnosis of DMDD than bipolar disorder in the DSM-5 (4). The sorting out of treatment algorithms for pediatric patients with more classical symptoms of bipolar disorder as compared to symptoms that are more likely to now be diagnosed as DMDD remains a challenge.

Lithium (Lithobid, Eskalith)

Clinical Applications and Empirical Support

The efficacy of lithium in the acute and maintenance treatment of and prophylaxis of children and adolescents with classic bipolar disorder has been demonstrated in case reports, open trials, and retrospective naturalistic studies (5–9). Geller et al. (10) conducted the first placebo-controlled study of lithium in children including 25 adolescents with various forms of bipolar illness and comorbid substance abuse. Although lithium was associated with improvements in overall functioning and a lower rate of substance abuse relapse, there was no difference between active and placebo groups on measures of manic or depressive symptoms. In children and teens with a BP-1 or BP-2 diagnosis and first treated with a combination of lithium and VPA, maintenance treatment with lithium was equal to VPA (11). As discussed earlier, the TEAM study demonstrated that risperidone was more effective than lithium for the treatment of mania in pediatric bipolar disorder (1). In this way currently atypical antipsychotics are first line treatment of acute mania in pediatric bipolar disorder but lithium is often used in combination with them (12,13). Taken together with the studies cited above, these data provide class B support for the use of lithium for the short-term or maintenance treatment of bipolar illness in children and adolescents. The presence of ADHD in children and teens with Bipolar Disorder (BD) may be a factor that leads to a diminished response either to lithium or VPA (14–16), although this was not shown in another study (17). After relapse on either lithium or VPA of youth with either BP-1 or BP-2, a prospective open study showed that 90% of youth responded to combination treatment (18). The treatment of acute depression in BP-1 in hospitalized teens with lithium is supported by a single open study with a response rate of 50% and a remission rate of about 30% (six youths with psychosis responded to lithium without AAPs) (19).

Other Clinical Applications

Aggression, a study comparing haloperidol, lithium, and placebo in 61 treatment-

resistant aggressive children (5 to 13 years) found that after 4 weeks of inpatient treatment, both haloperidol and lithium were superior to placebo in reducing aggressive behavior, and was associated with fewer side effects (20). Lithium was found to be superior (16 out of 20 responders) when compared to placebo (6 out of 20) in the treatment of aggressive behaviors in hospitalized children with conduct disorder (21). In contrast, a study of only 2 week duration failed to demonstrate efficacy in teens with conduct disorder (22).

TABLE 6.1.4.4.1

CLINICAL GUIDANCE ON MOOD STABILIZERS USED IN PEDIATRIC PRACTICE

Drug	Mechanism of Action	Main Indications and Clinical Uses	Dosage	Schedule	Advers
Lithium	Inhibition of phosphatidylinositol and protein kinase C signaling pathways; Enhancement of serotonergic transmission	Bipolar disorder, manic; prophylaxis of bipolar disorder; MDD aggressive behavior/conduct disorder; adjunct treatment in refractory MDD	10–30 mg/kg/day, dose adjusted to serum levels in the range of 0.6–1.1 mEq/l	bid/tid	Polyuri trem naus weig drow hair l effec and r funct long- adm child dehy highe acute toxic level can l threa
Divalproex	Inhibition of catabolic enzymes of GABA and of protein kinase C signaling	Bipolar disorder; aggressive behavior; conduct disorder; seizure disorders	15–60 mg/kg/day, dose adjusted to serum levels in the range of 50–125 mcg/L	bid/tid	Sedatic liver (requ and c mon thror panc
Carbamazepine	Inhibition of glial steroidogenesis; inhibition of alpha 2 receptors; blocks sodium	Bipolar disorder; complex partial seizures	10–20 mg/kg/day, dose adjusted to serum levels in the range of 4–14 mcg/L	bid	Bone n supp (requ and c mon blood dizzi drow rash liver espe 10 yr

Oxcarbamazepine	Channels block glial calcium influx	Seizure disorders	Maintenance dose of 18.5–48 mg/kg/day, not to exceed 2,100 mg/day		No rep marr supp beni inter com carb no bl mon nece
Lamotrigine	Weak 5HT3 inhibition; release of aspartate and glutamate	Bipolar depression and maintenance therapy; seizure disorders	75–300 mg/day	qd	Potenti threa Stev synd [dire [inve even

The Cochrane, Oxford team of Cipriani, Hawton, Stockton, and Geddes (23), conducted a meta-analysis to assess whether lithium has a specific preventive effect for suicide and self-harm in adults with unipolar and bipolar mood disorders. They reported that lithium is an effective treatment for reducing the risk of suicide in people with mood disorders, and this antisuicidal effect may relate to reduction in relapse of mood episodes. A additional mechanisms should also be considered, because there is some evidence that lithium decreases aggression and possibly impulsivity, which may be another pathway mediating its antisuicidal effect.

Mechanism of Action

Lithium affects several neurochemical systems, including serotonin, norepinephrine, and dopamine. However, its main actions appear to be mediated by effects on intracellular signaling processes, specifically of the phosphatidylinositol and protein kinase C pathways (24).

Pharmacokinetics and Drug Interactions

Lithium is readily absorbed from the gastrointestinal tract, and peak levels occur 1 to 4 hours after oral ingestion, depending on the formulation. Lithium carbonate is available in tablet and capsule, in two extended-release formulations (Eskalith CR, Lithobid), and a liquid form (lithium citrate). The liquid has the shortest T_{max}, and the sustained-release formulations have slower absorption and lower plasma peaks. Lithium is not metabolized in the liver, nor does it bind to plasma proteins, and approximately 95% of the ingested drug is excreted in the kidneys. The half-life in adults is approximately 24 hours, slightly longer than the 18 hours reported in children (25). This shorter half-life has the practical implication that reliable blood levels can be obtained in children after just 4 days (or approximately 5 × 18 hours), rather than the traditional 5 days required in adults. The shorter half-life in children

is due to faster glomerular filtration rates in the young. Because of their higher total body water, prepubertal children require higher weight-adjusted dosage than adults to achieve similar serum levels. Magnetic resonance spectroscopy has revealed that children have lower brain-to-serum concentrations of lithium as compared to adults, and they may require higher serum levels to achieve comparable brain levels (26).

Drug interactions occur at the level of the kidney. When given concomitantly, nonsteroidal anti-inflammatory drugs, tetracyclines, and thiazide diuretics can decrease urinary clearance of lithium and increase lithium levels and should therefore be used cautiously. By contrast, theophylline and caffeine promote lithium excretion, resulting in lower serum levels.

Clinical Management

Prior to initiating a trial of lithium, a child should have a physical examination, including screening laboratory tests such as a complete blood count, electrolytes, blood urea nitrogen, creatinine, and thyroid indices. In outpatient settings, dosing may be initiated at 300 mg twice a day for children and 600 mg twice a day for adolescents.

Weller (27) has developed a useful guide to approximate daily lithium dosing. For children under 12 years of age, dosages in the range of 10 to 30 mg/kg/day are typical. Thus, a 30-kg child would receive 900 mg/day in divided doses. Older adolescents are likely to be treated in the range of 1,200 to 1,800 mg/day during acute mania. Maintenance doses are typically lower.

Due to its narrow therapeutic index, lithium levels should be monitored closely. The optimal serum level range is in the range of 0.6 to 1.1 mEq/L. Serum levels should be drawn on average 4 days after a dose adjustment to ensure that a steady state has been achieved and 12 hours after the previous dose to ensure a trough reading (28). When used to treat bipolar illness, the clinical benefit of lithium may be evident within 10 to 14 days of reaching therapeutic serum level in some cases, although as many as 4 to 6 weeks of treatment may be required (29). Current recommendations include repeat laboratory tests at 6-month intervals. An increased white count in the range of 12,000 to 15,000 cells/mm (30) is common and without clinical significance. Thyroid-stimulating hormone (TSH) levels may increase in association with higher lithium levels and a higher baseline TSH (31), but thyroid hormone replacement is not generally recommended unless T4 levels start to decrease, or if clinical symptoms of hypothyroidism appear. Lithium levels should also be obtained when the patient's clinical status changes, if adverse effects occur, and routinely at 3- to 6-month intervals.

Adverse Effects and Toxicity

Lithium appears to be generally well tolerated in children and adolescents. Common

side effects include fatigue, nausea, diarrhea, abdominal distress, tremor, ataxia, aggravation of acne, cognitive dulling, and weight gain. Because lithium is excreted by the kidneys, it is generally not recommended in children with compromised renal function. The risk of glomerular damage with long-term lithium treatment appears to be minimal, but polyuria and polydipsia are relatively common due to lithium's effect on tubular reabsorption. Lithium-induced polyuria can generally be managed conservatively, either by reducing the total daily dose (when possible), by switching from a short- to a long-acting preparation, or by the addition of a low dose of a potassium-sparing diuretic such as amiloride. In a few cases, nephrogenic diabetes insipidus can occur, which may warrant discontinuation of lithium.

Signs of lithium toxicity can occur even at "normal serum levels." In mild forms, symptoms include nausea, diarrhea, impaired concentration, and muscle weakness. At serum levels above 2.5 mEq/L, multiple organs may be affected and toxicity may prove fatal. Because dehydration can increase lithium levels and may induce toxicity, parents and children should be educated about the importance of adequate fluid intake. Lithium has been associated with a small increased occurrence of tricuspid valve abnormalities and transient neurodevelopmental deficits in exposed newborns (32). Contraception should be encouraged in adolescents and treatment of a pregnant mother with lithium should weigh possible fetal effects against the adverse outcomes of an untreated mood disorder (33).

Valproate (Depakote, Depakene)

Clinical Applications and Empirical Support

Valproate is an anticonvulsant that has been shown to be an effective mood stabilizer in adults. Clinicians have utilized VPA in the treatment of a range of problems in children and adolescents, including bipolar illness and aggression associated with conduct disorder or oppositional defiant disorder. There are case reports and open studies that support the use of VPA in youth with conduct disorder, explosive behaviors, or impulsive aggression (34–37), and there are two small randomized clinical trials that support VPA efficacy in this population (38). There is less evidence supporting the use of VPA in acute or maintenance therapy of bipolar disorder in youth; two open studies showed a response rate of 50% to 60% (29,39) and a study in teens with mixed mania showed more than a 70% response (40). Studies involving VPA with atypical antipsychotics have yielded response rates of 80% or higher for the combination therapy (41,42). However, multiple clinical trials in pediatric and even preschool-age populations have suggested that risperidone is more effective than valproic acid as a treatment for acute pediatric mania (1,2). Treatment of ADHD after manic symptoms treated with VPA in children and teens showed that a mixed salt amphetamine did not worsen manic symptoms (43). In

conclusion, these emerging data provide a modest level of support for the use of VPA in the treatment of children and adolescents with bipolar disorder (class C support).

Mechanism of Action

VPA has multiple pharmacologic effects decreased dopamine turnover (decreased *N*-methyl-D-asparate currents, decreased release of asparate) (44), and the details of its therapeutic actions are not fully known. VPA enhances GABA-ergic inhibition through increased synthesis and release. Given the inhibitory role of GABA in the brain, this effect may account for the drug's anticonvulsant and antimanic effects. VPA also directly affect neurons by inhibiting sodium influx and increasing potassium influx (45). Additional research has found that it upregulates the FGF21 gene expression and promotes process elongation in glia by inhibiting HDAC2 and 3. This may further explain its mood-stabilizing and anticonvulsant effects (46).

Pharmacokinetics and Drug Interactions

There are three formulations of VPA: valproic acid (Depakene, capsule, and syrup), delayed-release divalproex (a combination of valproic acid and sodium valproate, Depakote, capsule, and sprinkle), and extended-release divalproex (Depakote ER). All formulations release the valproate ion in the gastrointestinal tract, and this moiety is responsible for the pharmacologic action. Absorption is more rapid in the liquid form, and it can be delayed in the enteric forms. The sprinkle form has a lower C_{max} and may have fewer gastrointestinal side effects. Slightly higher dosing (8% to 20%) is needed when shifting from VPA to the extended-release formulation (47). VPA has very complex metabolism. It is, therefore, not surprising that VPA has been noted to interact with medications of all classes. As monotherapy, VPA is metabolized mostly by beta-oxidation or conjugated via glucuronidation. Only 10% to 20% is metabolized via P450 cytochromes (CYP 2C9 and CYP2 A6). Children under the age of 10 years excrete less VPA-glucuronide and metabolize more VPA through the P450 cytochromes (48). When a potent CYP inducer (CBZ, phenobarbital, phenytoin) is added, more VPA shuttles through CYPs and more toxic metabolites are produced. Children under the age of 2 years who are on multiple inducing anticonvulsants, or who have congenital metabolic disease or organic brain syndromes, are more susceptible to developing hepatic failure. VPA is a moderate inhibitor of epoxide hydrolase, CYP 2C9, and some UDP-glucuronylsyltransferases (UGTs). It inhibits the glucuronidation of lamotrigine at UGT 2B7, increasing its blood levels and the risk of developing Stevens–Johnson syndrome (49, 50). In addition, VPA exhibits saturable protein binding (it has nonlinear pharmacokinetics), and it competes with many drugs for protein-binding sites (aspirin can displace it, VPA displaces CBZ).

Clinical Management

Prior to initiating therapy, a physical examination should be completed and laboratory screening studies including a complete blood count, liver function tests, and a pregnancy test for female teens should be obtained. Dosing in outpatient adolescents could start with 250 mg twice daily, and increased every 3 to 5 days in 250- to 500-mg increments to a target dose of 20 mg/kg/day in two to three divided doses. Younger children might start with half the starting dose used in adolescents and move up in 125- to 250-mg increments. Trough levels should be checked after steady state is achieved (3 to 5 days), and target serum levels are in the range of 45 to 125 μg/L. Clinical management involves monitoring weight, appetite, energy level, evidence of bruising or clinical symptoms of pancreatitis, and of androgenism in girls. Liver enzymes and a CBC should be obtained within the first month of treatment and periodically during chronic treatment (51). Reductions in platelets and white blood count can occur and should be carefully evaluated.

Adverse Effects and Toxicity

Gastrointestinal complaints, sedation, and (rarely) transient hair loss may accompany the initiation of treatment and may subside with continued dosing. Other adverse effects include increased appetite and weight gain, postural tremor, dizziness, asthenia, and cognitive dullness. Rare idiosyncratic effects can occur. VPA has also been associated with hepatic failure, and in children under the age of 2, with fatal hepatitis (see Pharmacokinetics and Drug Interactions). Early in the treatment, there is also a small risk of pancreatitis. Agranulocytosis is extremely rare. In women treated for seizure disorders, there have also been reports of polycystic ovary disease manifested clinically by hyperandrogenism, accelerated weight gain, and menstrual and lipid profile irregularities (52). The role of VPA in these adverse endocrine effects is unclear and a matter of some debate, especially among teenage girls. Studies in adult women with bipolar disorder have shown high rates of pre-existing menstrual abnormalities and increased testosterone levels with chronic VPA treatment (53). Clearly, monitoring weight and menstrual cycles are an essential component of clinical care in adolescent and adult females treated with VPA. VPA toxicity can be life threatening and may begin with increased tremor and confusion. It is associated with hyperammonemia, respiratory depression, and multiorgan failure (54).

VPA is associated with a variety of major and minor malformations in babies born to mothers taking VPA during pregnancy, including a 20-fold increase in neural tube defects, cleft lip and palate, cardiovascular abnormalities, genitourinary defects, and others (55). These effects appear to be dose-dependent (especially evident at doses above 800 to 1,000 mg/day) (56). Prior to initiating treatment with VPA in sexually active female adolescents, a negative pregnancy test and a reliable method of contraception should be documented.

Carbamazepine

Clinical Application and Empirical Support

CBZ is an anticonvulsant that has been used in adults for a variety of neurologic and psychiatric disorders, including seizures, trigeminal neuralgia, and bipolar disorder. It has demonstrated efficacy since the 1980s for the treatment of acute mania and prophylaxis of mania and depression in adults, but it was not until 2004 that it received FDA approval for the treatment of acute mania and mixed bipolar states in adults. Case series and open-label studies in children have included bipolar disorder (29,57,58), aggression (59), and treatment-resistant ADHD (60). To date, however, the one controlled CBZ trial in children failed to show its superiority over placebo for the treatment of aggression among 5- to 12-year-old inpatients diagnosed with conduct disorder (61).

Joshi et al. (62) conducted an 8-week, open-label trial of extended-release CBZ, as monotherapy in children with bipolar disorder. Of the 27 participating children with BD, 16 (59%) completed the study. CBZ-ER treatment was associated with statistically significant, but modest levels of improvement in mean YMRS scores (-10.1 ± 10.2, $p < 0.001$) with end-point mean YMRS score (21.8 ± 12.2) suggesting a lack of complete resolution of mania. They reported that open-label CBZ-ER treatment was beneficial for the treatment of BD in children. Weisler et al. (63) used pooled results from two randomized, double-blind, placebo-controlled trials into the use of extended-release CBZ capsules as monotherapy in bipolar disorder, to further reaffirm that CBZ-ERC is effective in the treatment of bipolar I disorder patients with either acute manic or mixed episodes.

Mechanism of Action

The mood-stabilizing effects of CBZ are not well understood: It decreases sodium influx and the release of glutamate; it inhibits adenosine A1 and dopaminergic activity; but it may also affect several types of calcium channels (64).

Pharmacokinetics and Drug Interactions

CBZ is available as an immediate-release formulation in tablets, chewables, and suspension, as well as in sustained-release formulations: an osmotic pump tablet (Tegretol-XR) and beaded extended-release capsules (Carbatrol, Equetro). CBZ is involved in an innumerable number of drug interactions, both as a victim substrate vulnerable to CYP inhibition and as an active inducer of CYPs and UGTs. As a substrate of CYP 3A4 and CYP 2C8, potent 3A4 inhibitors can affect CBZ (erythromycin). As an inducer of CYP 1A2, CYP 3A4, and glucuronidation, CBZ can induce its own metabolism and perhaps decrease the efficacy of the drug. The active

metabolite, CBZ 10,11 epoxide, can also be increased or decreased via drug interactions and can contribute to efficacy and toxicity. CBZ's free fraction can be displaced from plasma proteins by aspirin and NSAIDs, leading to toxicity. VPA can inhibit the epoxidation and glucuronidation of CBZ 10,11 epoxide.

Clinical Management

CBZ is slowly absorbed, and peak plasma concentration is achieved within 2 to 8 hours following oral administration. As an anticonvulsant, the initial dose of the immediate and extended-release formulation for children ages 6 to 12 years is 100 mg daily, and it can be increased at weekly intervals by 100 to 200 mg. The usual maintenance dose is 10 to 20 mg/kg/day, administered in divided doses (bid for extended, or tid for immediate formulations). Given the drug's short half-life following the induction of its own metabolism, frequent dose adjustments, especially in the first few weeks of treatment, are common. Pretreatment physical examination and laboratory studies should be completed, including complete blood count, liver function tests, and creatinine. Although there is scant evidence for an increase in major congenital anomalies in babies exposed to CBZ monotherapy in the first trimester of pregnancy (65), until further evidence is available, a pretreatment pregnancy test should be obtained in sexually active girls. They should receive counseling about appropriate contraception (as CYP 3A4 substrates, ethinyl estradiol, and progestins can be reduced through CBZ's induction of CYP 3A4). The clinical utility of therapeutic plasma levels for children with mood disorders is unclear. Trough plasma concentrations for anticonvulsant effect can be drawn after 4 to 5 days, and they may be maintained in the range of 4 to 14 μg/mL. These guidelines may be useful during dose adjustment and in order to prevent toxicity. CBCs and LFTs should be followed periodically. Sedation, gastrointestinal effects, and rash may occur. Leukopenia is common and rarely progresses to agranulocytosis. Very rarely, other bone marrow toxicities, liver toxicity, and inappropriate antidiuretic secretion syndrome may develop. Given the lack of controlled studies, the multiple drug–drug interactions, and its potentially serious adverse effects, CBZ should be considered as a third-line mood stabilizer in the treatment of children and adolescents and may be particularly useful as an alternative if there is morbid weight gain associated with lithium, VPA, or atypical antipsychotics.

Oxcarbazepine (Trileptal)

OXC is a CBZ prodrug metabolized through noncytochromal pathways to an active metabolite, monohydroxy derivative (MHD). In turn, MHD is minimally metabolized through CYP 3A4, and it is mostly glucuronidated and subsequently excreted in the urine. As a result, OXC does not show the auto-induction observed with CBZ, nor is

it vulnerable to potent 3A4 inhibitors, but like CBZ, it does possess a moderate ability to induce CYP 3A4 and some UGTs and to potently inhibit CYP 2C19. OXC may act through inhibition of voltage-sensitive sodium channels and modulation of potassium conductance and high voltage-activated calcium channels. OXC does not require the frequent blood monitoring associated with other mood stabilizers. However, a large multicenter, randomized, placebo-controlled trial of 116 subjects with pediatric mania failed to show any sign of improvement of OXC over placebo (66). In epilepsy trials, common adverse events include somnolence, headache, nausea and vomiting, dizziness, and rash (67). Like CBZ, there have been reports of inappropriate secretion of antidiuretic hormone (ADH) and Stevens–Johnson syndrome. Since OXC can induce CYP 3A4 and there is little information about fetal abnormalities, pretreatment pregnancy testing and appropriate contraceptive counseling are needed. According to the prescribing information, the recommended initial dose for youth 4 to 16 years of age with seizures is 8 to 10 mg/kg/day bid not to exceed 600 mg daily, and as monotherapy, a maintenance dose of 18.5 to 48 mg/kg/day not to exceed 2,100 mg/day (see product insert for dosing range by weight) but its use for pediatric mental health conditions should be minimal.

Lamotrigine (Lamictal)

In adults, lamotrigine has been shown to be effective in the treatment of BP-1 depression, to stabilize mood in rapid cycling BP-2 patients, and to provide prophylaxis for depression in BP-1 patients (68). In youth, a recently completed large, multi-center, placebo-controlled trial of lamotrigine for maintenance treatment for pediatric bipolar disorder failed to show statistically significant benefit of lamotrigine compared to placebo on the primary end point but did show some evidence of benefit on secondary outcomes. After initial open-label stabilization with lamotrigine subjects were randomly assigned to placebo or continued lamotrigine treatment, during the randomized phase the mean time to occurrence of a bipolar event (mania, depression, or mixed episode) for lamotrigine (as compared to placebo) was 155 versus 50 days for a depressive episode, 163 versus 120 days for mania/hypomania, and 136 versus 107 days for mixed episodes. The primary end point stratified log-rank analysis of time to bipolar event was not statistically significant; lamotrigine seemed particularly beneficial for adolescents with bipolar disorder rather than children in this trial. Lamotrigine has diverse actions on many neurotransmitters: It inhibits serotonin, norepinephrine, glutamate, and dopamine receptors, blocks calcium ion influx in N- and P-type channels, and stabilizes presynaptic neural membranes through sodium channels (69). Lamotrigine's pharmacokinetics are linear, and most of it is conjugated by the UGTs (UGT 1A4 and UGT 2B7). VPA inhibits its glucuronidation and decreases its clearance by about 50%. Conversely, UGT inducers (CBZ, ethinyl estradiol) can lower lamotrigine

levels by 50% (69). Lamotrigine is well documented to cause skin rashes that are usually mild and seen within the first months of treatment, but full-blown Stevens–Johnson syndrome (a potentially fatal condition associated with widespread skin sloughing) can develop. Rapid dose escalation and co-administration with VPA are risk factors, especially for children. A 10% rate for all rashes is commonly reported in adults (70). A recent review in adults suggests that slow dose titration and dermatologic precautions (limited antigen exposure) may reduce this rate (70). There are data suggesting a higher risk of major congenital abnormalities in babies exposed to lamotrigine in doses higher than 200 mg/day, and pending further studies, pretreatment pregnancy tests and contraceptive counseling should be made available to all pubertal girls (65). Toxicity is associated with lethargy, vomiting, ataxia, vertigo, and tachycardia, but only rarely is the outcome serious (71).

TABLE 6.1.4.4.2

CLINICAL GUIDANCE ON ANTIENURETIC AGENTS USED IN PEDIATRIC PRACTICE

Drug	Mechanism of Action	Main Indications and Clinical Uses	Dosage (mg/d)	Schedule	Adverse Effects
Desmopressin[a]	Antidiuretic hormone analogue	Enuresis	10–40 meg	qhs/bid	Headache Nausea Hyponatremia and water intoxication at toxic doses
Oxybutynin	Antimuscarinic agents		5.0–15	bid/tid	Anticholinergic side effects
Tolterodine			1–2	bid	Less anticholinergic effects, less sedation

[a]Can be useful for acute situations (e.g., sleepaways).

Topiramate (Topamax)

Topiramate is a glutamate-release antagonist, a GABA reuptake inhibitor, and it reduces activity at sodium and calcium channels (72). Most of topiramate is excreted unchanged through the kidney, and therefore, plasma levels will be lower in younger children because of their higher glomerular filtration rates. About 30% is handled by the CYPs and UGTs, and these pathways can be induced when the potent-inducing antiepileptics (CBZ) are added, leading to a doubling of topiramate's clearance. Topiramate modestly inhibits CYP 2C19, and when combined with higher doses of phenytoin, the concentration of the latter drug can be significantly increased. At topiramate doses at or above 200 mg/day, the concentrations of ethinyl estradiol and/or progestins in oral contraceptives can be decreased. Topiramate has been shown to be ineffective in acute mania in adults (73), and as a result, research efforts

in youth with mania were largely discontinued (72). Decreased appetite and nausea appeared as the most common adverse events in a discontinued trial in pediatric mania, as did weight loss, especially in some overweight subjects (72). Based on this observation, there has been additional clinical trial data suggesting that topiramate may be effective in reducing antipsychotic associated weight gain (74). Topiramate may be associated with cognitive blunting and word retrieval difficulties. Its use in bipolar disorder in youth as monotherapy cannot be endorsed.

Gabapentin (Neurontin)

This agent undergoes virtually no hepatic metabolism, and it is excreted largely unaltered by the kidneys. Despite a benign side-effect profile among adults, aggressive behavior and worsening hyperactivity have been reported among 12 children receiving gabapentin for the treatment of seizure disorders (51). Studies in adults as monotherapy in bipolar disorder have not demonstrated efficacy. Consequently, its use as a mood stabilizer for children cannot be recommended.

ANTIENURETIC AGENTS

Desmopressin, Oxybutynin, and Tolterodine

Table 6.1.4.4.2 depicts the pharmacologic characteristics of medications used for enuresis. Desmopressin (DDAVP) is a synthetic ADH, a powerful inhibitor of the production of urine. It can be administered orally or via intranasal spray. One review suggested that desmopressin helps approximately 25% of children who use it, with minimal risk of adverse effects (75). Although desmopressin is usually well tolerated, the beneficial effects often do not endure over time. The most effective treatment for enuresis is the use of behavioral interventions, such as a “pad and buzzer” or a “moisture alarm.” However, DDAVP can be a useful short-term adjunct, as in the facilitation of sleepovers or overnight camp stays. For longer-term pharmacologic management of enuresis, usually in cases unresponsive or only partially responsive to behavioral interventions, antimuscarinic agents can occasionally be useful. Alternatives to the time-tested use of low (25 to 50 mg HS) (76) or regular dose imipramine include oxybutynin (Ditropan) or the less sedating tolterodine (Detrol). As is the case of other pharmacologic interventions for enuresis, beneficial effects usually disappear rapidly upon drug discontinuation (Table 6.1.4.4.2).

6.2 PSYCHOTHERAPIES

CHAPTER 6.2.1 ■ PSYCHOTHERAPY FOR CHILDREN AND ADOLESCENTS: A CRITICAL OVERVIEW

V. ROBIN WEERSING, PAULINE GOGER, AND KATE L. CONOVER

The study of psychotherapy in youth dates back to the dawn of therapy itself—to the anxieties of Little Hans (1) and young Peter (2)—and to the beginning of both psychoanalysis and behaviorism. Since these first, seminal case reports, research in child and adolescent therapy has morphed considerably in form and the scale of research has grown exponentially. Over time, the dominant method for investigating therapy effects has become the clinical trial—in essence a psychotherapy experiment including manualization of the "independent variable" of therapy, randomization to treatment conditions, and use of standardized symptom-focused outcome assessments. At last review, thousands of these randomized studies had been conducted (3), and the youth therapy research base grows markedly with every passing year.

In this overview chapter, we aim to provide a brief summary of the main findings across this large literature, focusing on three main questions. First, *can* psychotherapy work? That is, under ideal, experimental conditions, is psychotherapy *efficacious* for youth and families? Second, *does* psychotherapy work? That is, in real-world clinical settings and samples, do we have evidence that psychotherapy is, in fact, *effective* in practice? And third, *how* does psychotherapy work? That is, do we have any substantive evidence on the underlying *mechanisms* of action of therapy effects? Our treatment of the questions of efficacy, effectiveness, and mechanism will be necessarily broad and is designed to highlight progress to date and critical areas for further research.

CAN PSYCHOTHERAPY WORK? THE QUESTION OF EFFICACY

A Historical Overview

The first summary review of the effects of youth psychotherapy appeared over 60 years ago. The author, Eugene Levitt, reviewed the existing evidence base of 18 studies treating "neuroses" in youth and came to a startling conclusion: There was little to no empirical evidence to suggest that psychotherapy was beneficial, and, indeed, the recovery rate for child and adolescent psychotherapy might be marginally worse than the simple improvement observed with the passage of time. In combination with the Eysenck (4) review of adult therapy, the Levitt (5) review and follow-up report (6) produced intense debate in the field. Many of the critiques

focused on the methodologic weaknesses of the psychotherapy studies that served as a basis for the author's negative conclusions. Early therapy efficacy studies typically: (a) failed to randomly assign youths to treatment and control conditions; (b) used nonequivalent comparison groups, such as therapy dropouts, as control conditions; (c) failed to specify what therapy procedures were used in the intervention being tested; (d) allowed therapists or other nonmasked raters to assess outcome; and (e) enrolled very heterogeneous samples of youth in terms of diagnoses and developmental level (see Kazdin (7) for review). These characteristics of early efficacy research substantially weakened the internal validity of the designs and made it difficult to impossible to interpret results, whether positive or negative.

In response to these critiques, the design of the prototypical therapy efficacy study evolved into that of the experimental *clinical trial,* characterized by explicit inclusion and exclusion criteria, random assignment, blinded and standardized diagnostic assessment, and manualized treatments. Within two decades, the evidence base of 18 studies available to Levitt had expanded to include over 100 clinical trials, and this explosion of therapy research coincided with the advent of modern meta-analytic methods for summarizing research findings. Together, these two developments provided a unique opportunity to revisit the conclusions of Levitt (5,6), and beginning in the 1980s several major meta-analyses were published on the efficacy of therapy in youth.

Evidence from Meta-Analysis

In *meta-analysis,* traditional narrative reviews of a research area are supplemented by a quantitative analysis of empirical findings across studies. As in a narrative review, meta-analysis begins with an exhaustive, well-documented literature search, with predetermined criteria for study inclusion and exclusion (e.g., requiring a minimum sample size). Following this collection of studies, researchers develop a coding scheme to capture the critical characteristics of each study, establish the reliability of the system, and code the findings from each investigation. Next, the empirical results of each investigation are transformed into a common metric of *effect sizes,* and these effect sizes form the unit of analysis for subsequent statistical tests. Statistical analyses range from simple estimates of a population effect size in a set of homogeneous studies to multivariate models designed to explain variability in effect sizes across a complex literature.

In psychotherapy meta-analyses, the most common effect size metric is Cohen's *d* (8). If the relevant summary statistics are reported in the published study, *d* is very simply calculated by taking the mean of the treated group on a measure of interest (e.g., depression symptoms at posttreatment), subtracting it from the mean of the control group, and then dividing this difference by the standard deviation of the control group (see Smith et al. (9) for other estimation techniques). This process

creates a score indicating how "far apart" in outcomes a therapy condition is from a control group, expressed in standard deviation units. By convention, a *d* of 0.2 is considered a small effect size, while a *d* of 0.8 is a large effect (10).

Casey and Berman (11) were the first to apply meta-analytic methods of this kind to the child psychotherapy literature in 1985. They reviewed and coded 64 controlled studies of therapy for youth (age 12 and under) and found that the average effect size for psychotherapy was a very respectable 0.71.

Since the Casey and Berman (11) report, four additional major meta-analyses have been published (12–15), with the most recent of these spanning 50 years of intervention research and including 447 clinical trials (15). Across these meta-analyses, youth therapy had medium to large effects on symptoms, with results similar in magnitude to effect size evidence from the adult literature (9). Furthermore, the confidence intervals around these population estimates did not cross zero, suggesting that, as a whole, psychotherapeutic interventions for youth were more efficacious than control conditions (typically a waitlist or no treatment control). The most recent and comprehensive meta-analysis by Weisz et al. (15) estimated the overall effect of youth psychotherapy to be 0.46 at posttreatment, with effects maintained over follow-up. This effect size is the most modest of the major meta-analyses, notably smaller than the effect reported in the original Casey and Berman paper. Further, Weisz et al. probed for moderators that might predict this apparent decrease in effect size in the literature over time. Of the candidate moderators, it appeared most likely that this decrease may be a function of more modern methods of calculating effect size, using a sample size correction to weight Cohen's *d* (see 16); recalculation of effect sizes from a 1995 meta-analysis also by Weisz using this method yielded a very similar effect size (0.54 vs. 0.71 for an unweighted effect size (14)).

While these broad-based meta-analyses have been consistent in their finding of an overall positive effect for youth psychotherapy, findings have been more mixed on whether therapy is efficacious across types of problems, treatments, and youth and family characteristics. Throughout the 1990s, type of youth problem did not emerge from these analyses as being significantly related to the magnitude of therapeutic improvement (12,14). In these analyses, youth problems were typically categorized into two broad bands—internalizing problems such as depression, anxiety, and somatic complaints and externalizing problems including disruptive behavior, delinquency, conduct problems, and attention/impulsivity. In the more recent Weisz et al. (15) analysis, these broad syndromes were decomposed into the four primary presenting problems seen in outpatient care of youth—anxiety, depression, conduct problems, and ADHD—with an additional category of "multiple problems" also coded. In this analysis, problem type emerged as a powerful predictor of a study's effect size. Trials testing psychosocial treatments for anxiety had significantly larger effect sizes (mean ES = 0.61) than studies targeting any other problem type. Effects for ADHD and conduct problems had the next largest effect sizes, with depression

trials having the smallest effects of any of the "big four" problem areas (mean depression ES = 0.29). Studies targeting multiple problems reported even smaller ES values, with the mean effect size estimate for this category of studies not significantly deviating from zero.

Interestingly, although problem type was found to significantly impact effect size, other person-level factors have not been consistently supported as moderators of efficacy in meta-analyses. In the large Weisz et al. (15) pool of studies, treatment did not seem to be differentially beneficial for children versus adolescents, girls versus boys, or Caucasians versus minorities—with the caveat that only 12% of the studies consisted of a non-Caucasian majority sample. The need for more diverse samples in clinical trial research is well documented. In a 2005 review of the methodological characteristics of youth treatment research, fewer than half of the investigations identified the race or ethnicity of study participants and only 25% reported on participant socioeconomic status (16).

In terms of treatment type, the five broad-based meta-analyses do support the overall conclusion that behavioral interventions produce significantly larger effects than nonbehavioral interventions. Some analyses suggest an unqualified superiority of behavioral therapies (14), while others suggest that the heightened value youth-focused behavioral interventions lies in the consistency of positive effects found across reporters (e.g., youth, parents teachers) compared to interventions with more variable effects across reporters. In the meta-analyses probing treatment type, "behavioral treatments" typically include such direct behavioral techniques as teaching parents more effective discipline styles or exposure for youth anxiety, as well as cognitive-behavioral techniques (CBT), such as helping depressed youth to label and correct unrealistically negative thinking and self-talk. Nonbehavioral psychotherapy has been conceived as a broad category including traditional psychodynamic-based approaches, client-centered therapies, and discussion groups. Notably, this division does not characterize well several treatment programs of fairly recent vintage that have significant empirical support, such as interpersonal therapy (IPT) for adolescents with depression (17) or Multisystemic Therapy (MST), a behavioral-family systems approach for juvenile justice-involved youth (18). Also note that some treatment modalities used with youth, such as family therapy (e.g., Multidimensional Family Therapy, 19) or group therapy could be characterized as either behavioral or nonbehavioral depending on the content of the intervention.

Not surprisingly, the finding of superior outcomes for behavioral treatments has been hotly contested, and a host of alternate explanations proposed (20). Differences between treatment types have previously been robust in analyses controlling for other potentially confounding differences between behavioral and nonbehavioral studies that might spuriously produce this effect, such as differences in problem type, severity of symptoms, or methodology (see Weiss and Weisz (21) for discussion). While many posit that behavioral treatments are superior, there are two critiques of

this position that cannot be tested in the current clinical trial literature base and remain as possible alternate explanations of this effect: (a) far more clinical trials of behavioral therapies have been published, and additional research on nonbehavioral therapies may yet yield more positive results; and (b) nonbehavioral therapies have been used as control conditions in some studies by investigators, and these treatments may not have been implemented with the same care and vigor as the main behavioral treatment being tested by the study, artificially lowering estimates of nonbehavioral therapy effect sizes (22). These possibilities speak to the chapter (Ritvo/Psychodynamic Principles in Practice) on psychoanalysis and psychodynamically informed psychotherapies, and the growing efforts within the analytic research community to conduct high-quality clinical trials of insight-oriented therapeutic approaches (23,24). However, psychoanalysis and other nonbehavioral therapies may have a high hill to climb, given the volume of research on behavioral treatments and the consistency of positive effects. Evidence appears particularly strong for exposure-based treatments for the anxiety disorders (25–27), behavioral parent training for child oppositional behaviors (28; note that a major evidence-based update review of this literature is in progress (29)), and behavioral parent training and multisystemic treatments with strong behavioral components for adolescent conduct problems (29). The hill also may have been made steeper by the trend in the early 1990s for professional organizations in the mental health field to move beyond broad examination of the efficacy of therapy to begin identifying specific *evidence-based treatment* (EBT) programs for targeted diagnostic clusters.

The Movement toward Evidence-Based Treatment

In the early 1990s, evidence-based medicine was broadly defined as the practice of weighing the available scientific evidence when making decisions regarding clinical care (30). At around the same time, the Society of Clinical Psychology (American Psychological Association [APA] Division 12) formed a task force charged with "educating clinical psychologists, third-party payers, and the public about effective psychotherapies" (31). This effort resulted in a series of reports identifying evidence-based psychosocial treatments (EBT) for adults (31–33). Parallel efforts by the Society of Clinical Child and Adolescent Psychology (APA Division 53) and the Society of Pediatric Psychology (APA Division 54) led to the publication of major EBT reviews for children and adolescents (34,35). Indeed, the practice guidelines of major medical associations also have broadened their focus to consider, evaluate, and include psychosocial interventions into the standard-of-care for emotional and behavioral problems, sometimes as a first-choice intervention (36). In addition to these efforts driven by professional organizations, research groups have endeavored to define and identify EBTs for psychological problems (25,36–39).

As reviewed by Tolin (40), different groups use varying criteria when evaluating the strength of the support for an intervention's efficacy. In general, however, treatments are considered a well-established EBT if they have shown positive effects in a series of carefully controlled, prospective studies by independent teams of investigators. Most often, this is defined as clinical trials in which: (a) participants were randomly assigned to conditions, and (b) treatment was compared to a placebo or other established treatment. However, some groups consider a large series of well-controlled single case studies to be sufficient for the designation of EBT. A second class of EBTs, identified as "probably efficacious" (33), is supported by scientific evidence but has been subjected to less rigorous tests (e.g., comparison to a wait-list control group). Most recently, the Board of Directors of APA Division 53 argued that the previous practice of updating the evidence base roughly every 10 years was not sufficient in light of a fast-exploding youth psychopathology literature, and called for a more continuous practice of updates, addressing different problem types in nearly every issue of Division's 53 journal (41). Accordingly, criteria required to classify the level of an EBT were standardized for this purpose, and included important additions such as a "treatments of questionable efficacy" level—warning clinicians and clients of treatments that were indeed tested but which do not work (41). This showed a greater emphasis on methodologic sophistication, and the attempt to not only identify *if* treatments work, but *how* they work (see Figure 6.2.1.1 for illustration (41)).

Based on these criteria, EBTs have been identified for a wide range of social, emotional, and behavioral difficulties commonly experienced by children and adolescents. To date, well-established psychosocial interventions have been developed for adolescent depression (42), obesity (43), posttraumatic stress disorder (PTSD); (44), ADHD (45), substance abuse (46), eating disorders (47), disruptive behaviors (28,29), autism (48), enuresis (49), and anxiety (27), and probably efficacious EBTs have been identified for OCD (50), bipolar (51), self-harm (52). As discussed in the section on meta-analysis, behavioral treatments are 8 to 10 times more likely to be tested systematically than nonbehavioral approaches (16), and it is not surprising that the majority of EBTs identified by the various work groups are behaviorally, or cognitive-behaviorally, focused. Although the majority of therapeutic interventions focus on the child, many efficacious programs target the systems in which youths function (53), such as their families (functional family therapy; (54)) or the juvenile justice system (MST; (18)).

Well-Established
Treatment must be:
Superior to placebo or active control group or **equivalent** to other well-established treatment
Found efficacious by 2 or more independent research teams/settings

Probably Efficacious
Treatment must have:
2 or more studies with superior results compared to wait-list control group
1 or more study meeting well-established criteria

Possibly Efficacious
Treatment must have:
1 or more RCTs with superior results compared to wait-list or no-treatment control group
OR 2 or more efficacious clinical studies

Experimental
Treatment has:
No RCTs
1 or more efficacious clinical trials

Questionable
Treatment has been tested adequately and has failed to achieve superior results as compared to other treatments or control groups

FIGURE 6.2.1.1. Categories of evidence-based psychosocial treatment. (Adapted from Southam-Gerow MA, Prinstein MJ: Evidence base updates: the evolution of the evaluation of psychological treatments for children and adolescents. J Clin Child Adolesc Psychol 43(1):1–6, 2014.)

Currently, the EBT movement has reached beyond the professional exercise of identifying therapies with promising outcomes and moved into the domain of policy, by funding and shaping the content of youth mental health care in practice. Policymakers at the national (55–57) and international (58) levels have endorsed the importance of evidence-based mental health care, and US federal funding has been made available to clinical care providers to support the training of community therapists in EBT programs (59,60). However, even when providers in community settings intend to select evidence-based interventions, they often fail to identify evidence-based practices as such and may also incorrectly identify label treatments as empirically supported (61). Family and patient organizations have begun to advocate for access to mental health interventions with demonstrated effectiveness (62), and states have developed initiatives to support the use of EBT services (63). Research efforts, too, have increasingly begun to focus not simply on the *efficacy* of psychotherapy in controlled trials and laboratory environments, but also on building an evidence base for the actual *effectiveness* of therapy in practice.

DOES PSYCHOTHERAPY WORK? THE QUESTION OF EFFECTIVENESS

The news, thus far, has appeared good for those concerned with providing quality psychological services to youth and families. Psychotherapy for youth has effects of a

reasonable magnitude and progress has been made in identifying specific treatments most likely to be beneficial for particular problems and diagnoses. However, limitations in the conduct of psychotherapy research have left core questions unanswered, including whether the research that supports the benefits of youth therapy and forms the base of the process of identifying EBTs is applicable to everyday clinical practice. As explicated in seminal papers by Weisz et al. (64,65), the majority of therapy clinical trials take place under conditions substantially different from community treatment as usual (TAU). For example, clinical trials typically are based in university clinics, academic medical centers, and research laboratories with copious resources and support staff. Families are usually recruited to participate in the study and screened to identify the primary target problem under investigation. Therapists in a research study may receive extensive pre-therapy training in the treatment protocol, be closely supervised on protocol adherence, and carry a small caseload of homogeneous clients. Psychotherapy may be free, or clients may be paid to participate in the research therapy. And, as discussed earlier, clinical trials are far more likely to utilize behavioral treatments than nonbehavioral therapies, the latter of which are heavily used in typical clinical practice (66,67). These differences between psychotherapy research and community TAU may dim the rosy outlook on the benefit of child and adolescent therapy in two major ways.

The Effects of Community Treatment as Usual

First, clinical care may not currently be as effective as the psychotherapy clinical trial literature suggests. Very few of the thousands of studies of child and adolescent therapy have examined the effectiveness of the therapy program of a functioning service-oriented clinic. In the early 1990s, Weisz et al. searched the youth treatment outcome literature for studies of “real-world” psychological services (68). They found only nine studies of clinic TAU. Results of this small body of research stood in stark contrast to those of the hundreds of typical psychotherapy clinical trials included in meta-analyses. Whereas clinical trials reported consistently beneficial effects of therapy for youth, the mean effect size of the TAU studies was near zero.

Consistent with this pattern, Weiss et al. (69) found minimal effects of TAU delivered to disturbed school-aged youths by therapists hired through a local community clinic. TAU therapists were free to use whatever techniques and dose of treatment they viewed as best, and they averaged 60 individual sessions, 18 parent sessions, and 13 school consultations per treated youth. After this substantial dose of therapy, TAU youth outcomes were equivalent to the outcomes of youth who had been randomized to receive only academic tutoring. At 2-year follow-up, the authors were able to contact 95% of their original sample of participants (N = 112), and the outcomes of the two groups remained quite similar (70), arguing against a longer-term preventive benefit or “sleeper effect” for community TAU.

Similarly, large scale effectiveness studies of TAU in mental health care systems have yielded ambiguous results at best. In the massive Fort Bragg investigation, efforts to boost the effectiveness of youth mental health care by coordinating TAU services did not lead to improved outcomes over uncoordinated care (71–73). One explanation of this finding is that the original community TAU elements were not effective to begin with and, thus, synergies between these services impossible to achieve (74). Dose of care also was unrelated to outcome in the sample, further suggesting that the original TAU elements may not have been potent (75,76). In contrast, the longitudinal Great Smoky Mountains Study (77) found that community TAU appeared to deflect the worsening trajectory of already impaired youth, a result interpreted as evidence of effectiveness of services.

These modest findings have reinforced calls by many (78) for a broad effort to reform mental health care practice by exporting EBTs from clinical trials into the community. This prescription relies on the assumption that it is differences in treatment type that account for the superior outcomes of psychotherapy in clinical trials compared to therapy in practice. Certainly, evidence from meta-analyses suggests that this assumption is plausible and that behavioral EBTs may perform robustly in the samples and settings of real-world clinical care. However, this hypothesis has only been tested within the last 15 years, and there are reasons to suspect that the effects of EBT may be attenuated in practice.

The Effectiveness of Research Treatments in Practice

The second implication of the differences between clinical trial research and typical clinical care is that promising EBTs may not work as well when tested under conditions more closely approximating real life. In addition to difference in treatment type, clinical trials and community care may vary along a number of sample and setting factors. For example, clinical trials for youth depression historically have included: (a) youth either “at risk” for depression or exhibiting only mild depression symptoms (79,80); (b) youth recruited from schools and newspaper advertisements rather than ascertained through clinical referral routes (81); and (c) youth carefully screened to possess a minimal number of comorbid psychiatric problems (82)—a sample of young patients *not* representative of community mental health practice (83). Preliminary investigations of patient factors related to depression treatment outcome have suggested that these three characteristics of research samples may predict therapy success (84), and, thus, treatment effects for more severe, comorbid clinical samples of depressed youth may not be as positive as clinical trial data would suggest. There may be a similar level of mismatch between the samples of youths enrolled in clinical trials of anxiety disorders compared to anxious youths in community clinics (85). Clinical trial research on disruptive behavior problems may fare better in terms of research-practice sample comparability, in part because of the

efforts of many investigators to recruit research participants from settings such as juvenile justice (53) and foster care (86).

Again, meta-analysis has proved a useful tool to generate hypotheses about the "robustness" of EBTs if transported to practice. Shadish et al. reanalyzed data from several previously published meta-analyses on the effects of psychotherapy in a mega-analysis of the adult and child literature (87,88). Studies were coded in terms of "clinical representativeness"—the extent to which the therapists, setting, and sample of the investigation were similar to active clinical practice. The authors clustered studies into tiers of representativeness and explored whether effect sizes for clinical trials decreased as study characteristics became closer and closer to real-world conditions. Overall, the authors found that effect sizes were constant across levels, but they also found only one study that fulfilled all of their clinically representative criteria. Interestingly, all of the studies included in the Weisz et al. (68) analysis of community TAU were screened out of the Shadish meta-analysis (87) on methodologic grounds, further highlighting the paucity of strong research probing the effectiveness of TAU compared to less active control conditions (e.g., a waiting list).

In a parallel analysis to their major broad-based meta-analytic report (15), Weisz et al. searched their pool of clinical trials for investigations that included (a) an active treatment condition utilizing an identified EBT from the Division 53 list of treatments, and (b) a community TAU comparison condition. They identified 52 trials that met these criteria and conducted a separate meta-analysis of this subgroup of studies to directly test the relative value of EBTs versus TAU (89). Overall, the EBT-TAU effect size was significantly different from zero and favored EBT (mean ES = 0.29). In this pool of studies, effect size did not significantly vary by problem type, although effect sizes were larger in studies of youths selected for having clinically elevated symptoms compared to studies where youths met diagnostic criteria for disorder.

In parallel, community agencies and governmental bodies have begun to systematically move EBT programs into practice. In the internalizing disorders, the greatest efforts and most progress have come in the dissemination and evaluation of treatments for PTSD. There has been a concerted effort to disseminate trauma-focused cognitive-behavioral therapy (TF-CBT) both nationally and internationally. The National Child Traumatic Stress Network (90) was established by the US Congress in 2000 and has grown to over 150 network centers located nationwide in university and community-based organizations. A major focus of the network has been the dissemination of EBT information and partnering with treatment researchers to provide certification in TF-CBT practices, including access to online training materials (91). In a recent review, it was reported that TF-CBT had been formally disseminated in 19 states and several nations (92), with recent trials reporting positive effects of TF-CBT over TAU services in Norway (93) and Zambia (94), and

positive effects using TF-CBT in a group format in a clinical trial in the Democratic Republic of the Congo (95). These dissemination efforts built on the base of clinical trials of TF-CBT that have long included elements of effectiveness research. From the very first trials of the intervention, active alternate treatments were used as a comparator, either usual community services or research conditions modeled on the content of typical community TAU for the disorder (see (96) for review).

In comparison, effectiveness and dissemination research in youth depression have been both more modest and less successful. Efforts to disseminate CBT for depression to community mental health settings have yielded negative (97,98) or weak results (99). EBT depression treatments have fared better when exported and tested in health settings, with IPT-A faring well in a trial based in school health clinics (17) and CBT for adolescent depression separating from usual care when delivered as part of a collaborative care model in primary care (100–102).

Efforts to probe the effectiveness of interventions for externalizing behavior problems are significantly more advanced. For many years, treatment researchers interested in disruptive behavior problems have turned to community agencies to ascertain their samples, and randomized effectiveness trials testing the effects of parent management training (PMT) and multisystemic therapy (MST) have been built on this community foundation. Studies testing the effectiveness of PMT in practice have been occurring on both the national and international levels, with accumulating evidence for the clinical and cost-effectiveness of this EBT compared to clinic TAU (103). In one of the most ambitious projects to date, Marion Forgatch and colleagues at the Oregon Social Learning Center partnered with the U.S. National Institute on Drug Abuse and the Norwegian Center for Studies on Behavioral Problems and Innovative Practice to study the adoption, adaptation and implementation of PMT in every community in Norway (104). The project aimed to evaluate adherence to the PMT model and assess whether fidelity to the core PMT treatment elements would prevent negative youth outcomes, such as substance abuse. In addition to these within-PMT analyses, agencies that were selected for PMT training were compared against matched control agencies in terms of therapeutic practices and child outcomes. These efforts were broadly successful, with youths treated with PMT evidencing greater behavioral change than TAU youths, and the intervention operating along the hypothesized mediational pathways specified in the PMT model (e.g., improved discipline, enhanced compliance (105)). Further analyses suggested that these PMT dissemination efforts maintained a similar magnitude of effects as original trials under more controlled conditions (106). The Norway implementation has become an exemplar of successful PMT dissemination and led to additional efforts and research projects in the Netherlands, Iceland, and Michigan (107).

In a similar large-scale fashion, Henggeler, Schoenwald, and the MST research team have conducted a series of community-based effectiveness studies and formed a nonprofit consulting company (MST services) to aid in the implementation and

evaluation of MST in real-world service agencies across the United States. MST was developed originally as an ecologic treatment for serious juvenile delinquency. Treatment is home based, targeted at the youth, family, and the surrounding environment, and the techniques employed draw heavily from behavioral and family systems theories (53) (see Adnopoz/Intensive Home-Based Family Preservation Approaches, Including Multisystemic Therapy). Initial efficacy outcomes were very promising, with statistically and clinically significant improvements in "hard outcomes," such as arrests and days in jail, compared to a variety of community TAU control conditions, including traditional juvenile justice services (108–110). MST also has been adapted and tested by the investigators as an intervention for substance-abusing youth, juvenile sex offenders, maltreated youths, and youths at risk for inpatient hospitalization due to serious emotional disturbance (111,112). Unsurprisingly, MST was a prime candidate for dissemination and had been transported into the service systems of 30 states and 8 nations by 2004 (113). The resulting body of program evaluation studies provides a unique dataset in which to examine the generalizability of EBT effects to a wide variety of practice settings and also to probe the sustainability of the intervention, when divorced from the original research team.

In a 2004 meta-analysis, Curtis et al. (114) reviewed 7 studies of MST, enrolling a total of 708 youth, and coded the extent to which the investigations more closely resembled efficacy research or a true effectiveness trial, embedded in real-world practice. Again, all youths in these studies were drawn from real-world referral sources, and the major indicator of the efficacy–effectiveness distinction was the identity of therapists and the mode of supervision. Three investigations utilized graduate student therapists, supervised by MST treatment developers, with extensive weekly reviews and feedback on audio or videotapes of sessions. In contrast, the effectiveness studies used community mental health providers who received initial training in MST but little ongoing supervision (by design, as sustainability of the program was a research question under investigation) (113). Effect sizes were significantly larger in studies utilizing graduate students as therapists (d = 0.81) than in studies with therapists from the community (d = 0.26). This meta-analytic result maps onto work done by the MST team examining the dissemination of the program to 45 sites, 400 therapists, and 2,000 treated youths, in which adherence to the MST model and strong quality assurance procedures are correlated with positive youth outcomes (115–117). Studies published after these reviews continue to support the likely effectiveness of MST in practice. In a recent trial in Sweden, MST provider adherence predicted client outcomes in MST, consistent with previous findings (118). Importantly, MST effects were recently replicated in an effectiveness trial by a research team that did not include the MST treatment developers. In this independent replication, MST was compared to services as usual for adolescents in the United States drawing from a sample of youths placed in self-contained

behavioral management classroom, separate from the general school population (119).

Taken together, results of these studies suggest that EBTs can be successfully delivered in community clinical contexts and often produce similar effect sizes as in the original efficacy trials. This first wave of effectiveness and dissemination research is transitioning to questions focusing on broader outcomes than symptom change (e.g., functioning, cost-effectiveness) and factors related to the initial uptake and sustainability of dissemination efforts in service settings (e.g., willingness to adopt new models, training and turnover, supervision; see (120) for a review focused on trauma treatment).

HOW DOES PSYCHOTHERAPY WORK? THE QUESTION OF MECHANISM

In our final section, we turn to the question of mechanism. Given evidence that psychotherapy for youth *can* work and that, under some conditions, it *does* actually work in practice, is there evidence on *how* psychotherapeutic interventions achieve their effects?

The brief answer to this query is no, due in large part to the content of most therapy manuals for youth and the design of most clinical trials. The majority of research therapies consist of multicomponent treatment packages. For example, a CBT manual for youth anxiety likely includes several of the following components: (a) teaching the child how to identify and label different emotions; (b) working to correct anxious self-talk and thinking; (c) teaching relaxation skills; (d) guiding desensitization of imagined feared objects; (e) participating in role-plays of coping skills; and (f) coaching the youth in real-life exposure to anxiety-provoking stimuli. From a design perspective, if a treatment utilizing a package of these techniques is compared to a waiting-list control and found to be more effective on global measures of anxiety, it is not clear whether every component of the treatment is necessary to produce therapeutic change. Additionally, in this hypothetical design, underlying pathogenic processes have not been assessed (e.g., shifts in anxious cognitions), nor tests conducted to determine if changes in these mechanisms mediate the impact of treatment on anxious symptomatology.

This example is intended as an illustration, yet it describes a fair proportion of the existing youth clinical trial literature. In 2002, Weersing and Weisz reviewed psychosocial clinical trials for anxiety, depression, and disruptive behavior cited in the Society of Clinical Child and Adolescent Psychology EBT reports (34). In this review of 67 studies, only 10% included an attempt to measure treatment processes and test whether change in these processes mediated therapy effects (121). Furthermore, these six investigations (122–127) suffered from significant methodologic limitations, such as failing to show that change in the proposed

treatment mechanism actually occurred before change in outcome, and one of the studies did not demonstrate mediation (123). While formal tests of mediation were very rare, simple measurement of possible mediators was much more common in the literature. Nearly every study of parent training assessed whether treatment impacted parenting behaviors, and the majority of depression studies included at least one measure of a potential treatment process (79%) (121). Overall, when EBT studies included these measures, investigators found that treatment significantly changed the process, at least when the process was assessed at posttreatment, along with the other general symptom measures of outcome. This pattern of findings is consistent with mediation of treatment by theoretically specific intervention processes, but it does not preclude other interpretations of results. For example, finding that parent training impacts both positive parenting behavior and child noncompliance may imply that changing parenting improves youth behavior; it also may be that improved youth behavior makes it easier to be a positive parent, and an alternate mediating process was responsible for changing youth noncompliance.

Unfortunately, in the 14 years since this last review, the literature appears to have moved very little. A recent volume by Maric et al. (128) sought to provide a comprehensive report of empirical evidence for moderators and mediators of youth treatment outcome. In our own contribution to this work on youth depression (129), we noted that only two additional mediation studies had appeared in the literature since last review (121), and these studies suffered from the same flaws as previous research in the area—effects of "mediators" measured primarily at posttreatment, inconsistent effects across different measures of mediators and outcomes, and over-reliance on self-report scales. Across disorders, mixed findings for putative statistical "mediators" were quite common (e.g., for anxious self-talk as a cognitive mediator of CBT (122,130)), and the problem of temporal precedence remained a central issue in interpreting even positive results (e.g., (131)).

As treatment mechanism research moves forward, it would seem valuable for psychotherapy investigators to employ more rigorous designs and to move beyond the traditional self-report, parent report, and behavioral observation rating scales that have long characterized assessment of youth therapy processes and outcome. It is notable how little the youth psychotherapy literature appears to have been informed by modern advances in developmental psychopathology, including the explosion of research on biologic bases of behavior (132). In the Weersing and Weisz review (121), the only studies to include putatively "biologic" mediators were early investigations of behavioral treatments for anxiety that measured indices of physiologic habituation such as galvanic skin response and heart rate. This is a far cry from mechanism studies assessing shifts in cortisol, brain activation, or the buffering effect of social support programs on genetic vulnerability to acute stress reactions (133), and a biologically based mediator of psychosocial treatment effects has yet to appear in the depression, anxiety, PTSD, disruptive behavior, or ADHD

literatures (128). In the next 50 years of youth psychotherapy research, it seems likely that these sorts of tests will move from conjecture to reality and substantially enhance our knowledge of why therapy is therapeutic.

CONCLUSIONS AND FUTURE DIRECTIONS

In sum, the available evidence suggests that (a) psychotherapy for youth can produce positive effects and is generally efficacious in research studies; (b) there may be a need to improve on the effects of typical community mental health care for youth; and (c) we may have the means to do so, through the careful dissemination and implementation of efficacy-tested EBT programs in practice. However, these general conclusions come with caveats. The number of rigorous studies of community TAU is quite small, and there is still a gap in efficacy research focusing on the insight-oriented and eclectic approaches typically used in practice. The body of EBT effectiveness trials is growing and outcomes appear promising, but coverage of internalizing problems is thin, and results from the better developed externalizing literature suggest that effect sizes of EBTs in practice may be moderated by adherence and quality control of interventions and therapist and organizational factors.

In addition, we still know remarkably little about how psychotherapeutic interventions work. This lack of precision is unsatisfying scientifically and may make the task of transporting these multicomponent research treatments into clinical settings more difficult than need be. If only one or two techniques of a complicated treatment package are producing change, then time spent training and providing the rest of the treatment package is wasted effort. Lack of understanding of mechanism also hampers our ability to develop new treatments that efficiently target core processes of disorder—a critical task, given evidence that the effect sizes for interventions in practice may be halved from efficacy estimates (114). In the next generation of psychotherapy research, a better understanding of why therapy works would seem to be of paramount importance.

CHAPTER 6.2.2 ■ COGNITIVE AND BEHAVIORAL THERAPIES

MENDY BOETTCHER MINJAREZ, RACHEL A. MONTAGUE, EMILY A. FOX, AND JOHN PIACENTINI

INTRODUCTION

Cognitive-behavioral therapy (CBT) is one of the most widely researched and evidence-based forms of psychotherapy today. Although CBT technically refers to a group of therapeutic interventions employing an integrated approach to both behavior and cognition, this chapter also covers interventions addressing each of these domains in a relatively isolated fashion (behavior therapy and cognitive therapy, respectively; all collectively referred to hereinafter as CBT). CBT can be differentiated from other psychotherapeutic approaches by its historical roots in experimental and learning psychology and by its ongoing emphasis on experimental validation of efficacy and treatment mechanisms. Over the past decades, CBT has rapidly progressed from a specialized intervention to a mainstream therapeutic approach that is now a mandated part of psychiatric residency training in the United States (1–3). This widespread acceptance is due in no small part to the fact that CBT is, by design, a problem-based, short-term, and contextually relevant treatment approach.

BACKGROUND AND HISTORY

Cognitive Therapy Foundations

Cognitive therapies are based on the notion that it is not events, but people's interpretations of events, that cause psychological disturbance. As such, therapy from a cognitive perspective focuses on identifying and changing people's cognitions as a way of changing their feelings and reducing psychological distress.

Behavior Therapy Foundations

When working within a purely behavioral framework, overt behavior is typically the primary concern or symptom. "Overt behavior that one can see" (4) is targeted through a variety of intervention strategies, and behavioral changes are thought to influence thoughts and feelings. Setting concrete goals and measuring specific behaviors is an integral part of this approach and is considered the primary means of evaluating progress and outcomes.

Cognitive-Behavior Therapy Foundations

Behavioral difficulties and other symptoms of disorders often result from a complicated interaction among thoughts, feelings, and behaviors. As such, treatment will often include both cognitive and behavioral techniques. For example, when trying to understand a behavior, it is possible that antecedents and consequences are covert, rather than overt. Covert variables are often internal and consist of cognitions or emotions. Thorough analysis of a behavior that involves covert variables will require that the clinician obtain detailed information about the patient's thoughts and feelings before and after the observable behavior. It has also been noted that while traditional behaviorists believe that changes in behavior result in changes in thoughts and feelings, this relationship can be reversed, such that changes in thoughts and feelings result in behavioral changes (4). As such, many symptoms and disorders are more thoroughly addressed by the combination of cognitive and behavioral techniques that is known as CBT.

COGNITIVE-BEHAVIORAL MODEL

Escape or Avoidance Conditioning

Much of CBT is based on gaining an understanding of why negative thoughts and beliefs persist and why behavioral cycles do not get broken over time. For example, it has been proposed that avoidance, escape, and safety-seeking behaviors (5) maintain anxiety because the individual does not have the opportunity to disconfirm beliefs by experiencing that the anticipated negative outcome does not occur when avoidance or escape is not allowed. Instead, they are led to believe that they did not experience danger because they made a good decision to avoid or escape. People who do not avoid situations may engage in other types of behaviors (safety-seeking behaviors) that allow them to believe that danger was avoided. For example, individuals who engage in compulsions in obsessive-compulsive disorder (OCD) are led to believe that their obsessive thought did not result in a negative outcome because they engaged in the compulsive behavior. Similarly, individuals who "take it slow" to prevent a heart attack in panic disorder believe that they did not have a heart attack because they modified their activity level. In these examples, individuals erroneously believe they prevented the feared situation from occurring by engaging in certain behaviors. Through this cycle, the preventative behaviors are reinforced, which confirms in the individual's mind that the anxiety was legitimate.

Attention-Related Factors

It has also been proposed that attentional factors play a role in disorders that can be

treated using a cognitive-behavioral model. For example, individuals with anxiety disorders, depression, and other disorders that involve disturbance in cognitions often selectively attend to cues that confirm or exacerbate their condition (6–8). For example, individuals with social phobia may be overly attentive to negative cues from others at the expense of positive cues, and individuals with panic disorder may attend closely to bodily sensations, which they then interpret as dangerous.

Cognitive Images

Cognitive images are often examined when viewing a disorder from a cognitive-behavioral perspective. Images of distressing events are common among all individuals; however, in individuals with pathology, these images are interpreted as signs of danger. For example, individuals with OCD may believe that thinking about hurting someone increases the likelihood that it will happen. As a result, they believe that something must be done to prevent the danger. Similarly, in posttraumatic stress disorder (PTSD), intrusive memories may frequently occur and are interpreted as a sign that recurrence of the trauma is likely.

Memory Processes

Memory processes may also play a role in disorders. For example, anxious individuals may have a tendency to recall situations that confirm their anxiety, such as a person with social phobia who recalls situations in which he or she performed poorly, but not those where he or she performed successfully. Finally, rumination may perpetuate and enhance fear (5). That is, thinking about an event may lead to the interpretation that the event is more likely to occur. Further, selective attention for negative past events may lead to the perception that they are more likely to happen again in the future. In contrast to some forms of cognitive treatment that involve reliving an event through imagery, rumination does not focus on constructive reprocessing of events. Rather, it focuses on elaboration that makes the event more abstract and, therefore, threatening. For example, an individual with PTSD may persistently ruminate about the event, while asking, “What else could I have done?” without realistically considering the limits of what a person is capable of doing.

Behavioral Conditioning

Many symptoms are also conceptualized as being caused or maintained by behavioral conditioning. Two types of conditioning may occur. In *classical conditioning* (9), a stimulus (unconditioned stimulus) that elicits a reflexive response (unconditioned response) is paired with a stimulus (conditioned stimulus) that initially elicits no response, but, over repeated trials, comes to elicit the same response as the original

unconditioned stimulus (e.g., Pavlov's classic study where dogs learned to salivate in response to a bell that had been paired with the smell of meat powder (9)). Phobias typically develop through a classical conditioning paradigm, as stimuli, which were previously neutral, are paired with a traumatic event, leading to future avoidance of stimuli related to that event. The subsequent avoidance behavior does not allow extinction to occur, thus, the phobia is maintained.

The classical conditioning paradigm is often used to explain other phenomena, such as emotional responses, addictions, and psychosomatic disorders. As a result, many treatments for these disorders are based on the notion of classical extinction. Extinction occurs once the connection between the conditioned stimulus and the response has been established and the conditioned stimulus is then presented repeatedly without the unconditioned stimulus (e.g., the bell is presented without the meat powder). When this occurs, the conditioned response will decay over time because the reflexively reinforcing stimulus is no longer available. Therapy techniques that are associated with classical conditioning and classical extinction include counterconditioning, systematic desensitization, covert sensitization, and exposure and response prevention (ERP).

Principles of *operant conditioning* are based on the work of B.F. Skinner (10,11), who demonstrated that new behaviors could be shaped through reinforcement (a behavior followed by a positive consequence is likely to occur again) and its subsequent removal (when reinforcement is removed, the behavior will decline, or extinguish, over time). Principles of operant conditioning also often maintain symptoms (e.g., negative behaviors that are reinforced by maladaptive parenting cycles in attention-deficit hyperactivity disorder [ADHD] and behavioral disorders; food restriction is reinforced by weight loss in eating disorders). These principles are also often used in cognitive-behavioral treatment, as reinforcement can be used to increase or strengthen positive or adaptive behaviors, while punishment and extinction can be used to decrease negative or maladaptive behaviors.

CLINICAL CONSIDERATIONS IN USE OF CBT WITH CHILDREN AND ADOLESCENTS

Generally speaking, the patient–therapist relationship in CBT treatment has been referred to as one of "collaborative empiricism" (12–15). This relationship is characterized by a high degree of collaboration and a "scientific attitude" (13,16,17) toward testing the validity and accuracy of the patient's cognitions and behaviors. That is, the cognitive-behavioral therapist typically works as a team with the patient to examine and understand thoughts, feelings, and behaviors. This is done by developing hypotheses about thoughts and behaviors, collecting data on those thoughts and behaviors, examining patterns, and generating alternative, more adaptive, ways of thinking and behaving.

When working with children and families, however, certain factors must be taken into consideration with regard to this model. For example, children may have difficulty reporting on their thoughts, feelings, and behaviors. Further, parent and family thoughts, feelings, and behaviors may influence those of the child. As a result, the following areas are briefly examined with regard to engaging in cognitive-behavioral treatments with children and families.

Developmental Perspective

Adopting a developmental perspective when working with children and adolescents is critical for effective intervention planning. Several developmental considerations are suggested for use when doing CBT with children. First, the child's level of autonomy and independence must be taken into consideration. The child's autonomy is important both in terms of giving older children and adolescents enough autonomy in setting and following through with their treatment goals, and in making sure that younger children have enough support from parents and other involved individuals. As such, it is also important to consider what other individuals or systems are involved in the child's life and what their role should be in therapy. Further analysis of how other individuals and other family or systems variables may be maintaining the child's difficulties is an important clinical consideration. That is, families, schools, and other systems may have adapted to a child's symptoms in ways that actually maintain, rather than decrease, the difficulties. Parent, teacher, and other adult-focused training is often necessary in addition to individual therapy sessions with the child (4). Involvement of these individuals may also facilitate practice and generalization in the natural environment, which produces more rapid and enduring effects than treatment that only occurs during therapy sessions.

Adapting CBT treatment concepts to the appropriate developmental level is important as well. For example, efforts to address the cognitive biases and distortions underlying a number of psychiatric disorders (e.g., anxiety, depression) can be complicated by the lack of strong abstract thinking skills in most young children. To address this limitation, multiple strategies have been developed to concretize target cognitions and abstract concepts (18). For example, symptoms can be characterized as persona that the child can relate to, such as the "Bad Thought Monster" who must be conquered (19). Similarly, obsessions in OCD can be understood as external and can be blamed on a pesky bug, named "OC Flea" (20), whose ideas must be resisted. Children can also be encouraged to play the role of detective or to team up with a detective in testing assumptions and beliefs (19). These types of developmentally appropriate adaptations assist children in understanding concepts that are otherwise verbally explained in therapy with adults, which may exceed the developmental capacity of children.

With very young children, cognitive-behavioral play therapy (CBPT) may be

indicated, as it embeds cognitive-behavioral strategies into play-based interactions (21,22). As young children may have difficulty understanding concepts in CBT, CBPT allows teaching and therapeutic work to occur in play. The primary mechanism for teaching concepts is modeling, which has been shown to be effective in teaching new behaviors (23). Many different CBT concepts can be modeled with puppets or other toys, such as demonstrating that a puppet gets over his fear gradually the more he enters into a situation. CBPT also involves some adult administration of CBT concepts, such as scheduling activities for a withdrawn child.

Other developmental considerations include the child's age, language level, cognitive ability, and the intensity, duration, and frequency of the symptoms. It has been suggested that younger children benefit more from behavioral techniques than cognitive ones, especially because they often have difficulty reporting cognitions that accompany symptoms and behaviors. Cognitive techniques that younger children have benefited from include relaxation training, imagery, and positive self-talk. Children over the age of 9 are thought to have increased capacity for reporting and understanding cognitions and may begin to benefit from more sophisticated cognitive aspects of treatment. Each child must be individually evaluated, however, as other factors, such as language level, may cause cognitive techniques to be difficult for older children, as well.

Family-Related Factors

The Role of Families and Other Systems in Cognitions and Behaviors

Because CBT interventions place an emphasis on antecedents and consequences of behaviors, avoidance behaviors that maintain symptoms, and other factors that may be affected by the environment, the role of family and other relevant systems is critical in assessment and treatment planning in CBT (24,25). Depending on the nature of the symptoms, it is likely that others in the child's life are making accommodations that support and maintain, rather than discourage, the maladaptive behaviors (26). For example, in a child with OCD, the family may tolerate extensive rituals that interfere with daily routines to avoid temper tantrums that might result from setting limits on ritualistic behavior (27,28). As such, careful analysis of the child's symptoms within family, school, and other relevant contexts is critical for CBT treatment planning with children and adolescents.

Parent/Family Involvement in Therapy

Families play a pivotal role in therapy for children in several ways. First, it is often important to have information about family context and parental cognitions, emotions, and behaviors to better understand the child's symptoms within a cognitive-behavioral framework. Changes in family routines, dynamics, and discipline

practices may be critical in facilitating changes in individual child-focused symptoms. Young children, in particular, may need ongoing assistance from parents and other relevant adults to follow through with treatment goals and homework. Moreover, with older children, families may need to learn to allow the child or adolescent to take responsibility for treatment goals and homework, which may require the family to decrease their level of involvement. These factors must be considered when deciding whether to work with a child individually, a parent individually, or with the child in conjunction with family members.

Older children and adolescents often attend therapy sessions individually, and parents are informed during the latter portion of the session about session content and subsequent homework that is to occur between sessions. It is sometimes necessary to work individually with parents, however, especially with young children who are having behavioral difficulties.

Finally, the child's symptoms are often a significant source of family stress and parent–child conflict. In these cases, it can be beneficial to work individually with the child and/or the parents. It is sometimes helpful to instruct that parents not remind their child about therapy homework and treatment goals, rather that performance be evaluated by the child and the therapist during sessions. This tactic can be useful in decreasing negative parent–child interactions, especially with adolescents, until symptoms have decreased.

GENERALIZATION AND MAINTENANCE

Three types of generalization are important to consider in CBT interventions with children. These are (a) generalization across settings; (b) generalization across functional domains (behavior, cognitions); and (c) generalization over time, which is termed maintenance. Generalization and maintenance must be considered with regard to intervention strategies, as well as improvements in functioning. That is, for successful change, the patient must use the techniques learned in session across settings, learn to apply them to a variety of domains, and continue to use them over time for as long as necessary. Similarly, when change begins to occur, it is important that the change is observed across settings (not just in the therapy setting), that change in multiple domains occurs, and that the change is maintained over time.

Kendall and Lochman (29) propose several strategies for promoting generalization and maintenance of improvements in functioning when using CBT strategies with children. First, rewarding behavior change using attainable goals that are applied across an increasing number of settings over time may be useful. These goals should be reinforced in each successive setting, and reinforcement should only be faded when the behavioral change appears stable and lasting.

Treatment length is also an important consideration in programming for maintenance of changes made in therapy. A period of 3 to 6 months is most common

(13); however, it has been suggested that 6 months or longer may be most effective. It has also been suggested that length of treatment over time may be more important than the number of sessions (30), and intensity may be an important factor, as well (31). Thase et al. (13) suggested that unsuccessful therapy should generally not continue beyond 12 to 16 weeks for outpatients. Use of behavioral rehearsal (e.g., role playing) to emphasize use of techniques in specific situations has also been proposed as an important mechanism for generalization of skills. That is, once a child has learned the concept of a skill, the likelihood that the skill will be used outside therapy in an actual situation is increased if the child has had opportunities to practice it under low demand, low stress circumstances. Role-plays can then be used to assist the child in refining skills to fit increasingly specific situations.

Finally, generalization is promoted when the child is taught skills that apply to multiple behaviors and situations, such as problem-solving processes, rather than specific behaviors. For example, self-instruction training has been proposed as a means of promoting generalization of skills, especially across settings and behaviors. Because self-instruction training involves having the child learn a series of steps in self-instruction of positive decision-making, this skill is considered more flexible than a series of specific steps that apply to a specific situation. In this way, the child can apply the steps to multiple problems in multiple settings.

Although these techniques may be helpful in generalizing skills across settings and over time, long-term data on such procedures are limited, especially with children. The mean duration of follow-up data is 5 to 7 months' posttreatment (32–35), with little available data to indicate outcomes over longer periods of time.

COURSE OF THERAPY

General Characteristics of CBT Treatment Plans

Some general aspects of treatment are characteristic of CBT regardless of diagnosis, age, developmental level, or other individual qualities, and are important for the patient to understand at the outset of treatment. According to Thase et al. (13), these are (1) the patient will be an active participant in trying new strategies; (2) the patient will be expected to complete homework; (3) therapy outcomes will be measured via data collection, and techniques will be modified if they are unsuccessful; (4) the therapist will actively guide treatment; (5) therapy will be time-limited; and (6) treatment strategies will be empirically based. When working with children, families may need to be incorporated in these treatment components. For example, it may be that the child and the parents must be active participants, rather than the patient alone.

CBTs are generally characterized by three phases of treatment. In the initial stage, the nature of the patient's presenting problem is assessed, rapport is established, and

psychoeducation (described later) occurs to prepare the patient for the active phase of treatment. Once the symptoms, related variables, and cognitive and emotional characteristics have been identified, a treatment plan is developed. This plan typically begins with psychoeducation of the patient about symptoms, cognitive behavioral understanding of those symptoms, and rationale for treatment. In the middle phase, active treatment occurs, which involves the acquisition, application, and mastery of cognitive-behavioral treatment strategies. This phase involves regular treatment sessions, as well as consistent homework. Over the course of treatment, goals and hypotheses about symptoms are re-evaluated and modified, as necessary, on an ongoing basis. The middle phase tapers off when symptomatic relief has occurred and the patient appears ready for maintenance and relapse prevention.

The final phase focuses on generalization and maintenance of techniques and relapse prevention. During this phase, the treatment schedule is thinned and the patient assumes greater responsibility for implementation of techniques on an ongoing basis. Finally, as necessary, “booster sessions” may occur after treatment has been completed to ensure that long-term changes are maintained.

Frequency and Duration of Treatment

CBT sessions typically occur once or twice per week in an outpatient setting. Generally speaking, it is important that enough time elapses between sessions for homework exercises to be meaningful. In inpatient settings, sessions may occur as frequently as once per day; however, the severity of illness is generally proportional to the frequency of sessions in such cases (i.e., the child is significantly ill to warrant daily monitoring and practicing of techniques). In general, it is recommended that the therapist decide on a case-by-case basis whether sessions should occur any more than once per week, as with any type of therapeutic intervention.

With some exceptions, CBT typically occurs over a 3- to 6-month period, with some type of tapering period near the final termination of therapy (13). Using clinical judgment, it is generally recommended that a tapering strategy be used in termination due to the need for generalization of techniques learned in therapy. That is, once termination has occurred, patients will be required to continue using strategies learned in therapy. Tapering the therapy can be a helpful way to monitor the patient’s success in using the techniques on an ongoing basis over increasing periods of time.

It is not uncommon for patients to require a brief “booster” session(s) after termination has occurred. In such cases, patients’ use of previously learned CBT techniques may have declined, or new unanticipated situations may have arisen that have resulted in a reoccurrence of symptoms. Frequently, patients do not require an additional full course of therapy; rather, they can benefit from one or several sessions to “refresh” their skills or to assist them with application of their skills to new problems.

Assessment for Treatment Planning

CBT treatment for any disorder must begin with a thorough assessment of the patient's cognitive, behavioral, and emotional symptoms. Assessments should address detailed information about the patient's symptoms (chief complaint) and identification of maintaining factors. Normalization of the patient's problems can be an important therapeutic aspect of the assessment phase, which may lead to immediate symptomatic relief. The goal of this phase should be to develop a cognitive-behavioral model of the presenting problem that can be used to guide treatment. Depending on the chief complaint, the initial assessment may include the following types of information:

- Descriptions of when the symptoms occur (time, place, circumstances, antecedents, consequences)
- Cognitions that accompany each symptom (may be different for different symptoms)
- Behaviors that accompany each symptom (may be different for different symptoms)
- Emotions that occur with each symptom (may be different for different symptoms)
- If cognitions and behaviors relieve symptoms, detailed description of how this occurs
- Information about factors that help or exacerbate the symptoms
- Maintaining variables: avoidance, escape, safety behaviors, attention/focus, dysfunctional/faulty beliefs, automatic thoughts
- Overall beliefs (cognitive schemas) that lead to cognitions, behavior, and feelings
- Previous treatment and treatment outcome
- Onset: including any possible causal factors that are not maintaining factors (e.g., traumatic event in PTSD, negative situation paired with stimuli in specific phobias)

It may be helpful to have the patient describe a recent event in detail, while asking specific questions to elicit information about thoughts, feelings, and behaviors (e.g., "What were you thinking when that happened?" or "How did your body feel at that moment?"). Sometimes it is difficult to elicit enough explicit information from children during a session, and homework is required as part of the assessment phase. Such homework might include writing down thoughts, feelings, and behaviors when certain events occur if the patient has difficulty reporting in session. It might also include having the patient or parent self-monitor the frequency of symptoms and associated variables. Once this initial assessment is complete, the patient's symptoms can be framed and described in terms of a cognitive-behavioral model and treatment can begin with psychoeducation.

Psychoeducation

Cognitive-behavioral interventions typically begin with some form of psychoeducation, which often continues throughout treatment. Psychoeducation is particularly important because many of the techniques utilized in CBT are driven by theoretical or empirical underpinnings that, when understood, allow the patient to better grasp *why* such techniques are being used and *how* change will occur, thus increasing motivation and follow-through. When working with children and adolescents, psychoeducation often occurs separately for children and their parents. This way, parents can have a more in-depth understanding of their child's treatment plan and children's psychoeducation can be developmentally appropriate to their age and cognitive level.

Psychoeducation may be conducted using a variety of procedures. Symptoms and related variables may be explained to individuals, and basic concepts may also be demonstrated. For example, when in the early stages of teaching patients that thoughts do not increase the likelihood of events occurring, *behavioral experiments* to demonstrate this point may be helpful (e.g., have the patient think about making someone else in the room stand up to demonstrate that the thought does not cause the event to occur). Bibliotherapy and Cognitive-Behavioral Play Therapy techniques may also be helpful, with young children in particular, to illustrate concepts and to educate about symptoms. These techniques may be particularly useful for young children who are resistant to change, as the focus is initially on the symptoms of the characters in the story or play, as opposed to the patient.

Psychoeducation often covers a variety of topic areas, as well. For many disorders, it is important to educate the individual about *physiologic* symptoms, which can lead to an immediate reduction in anxiety as they learn that such symptoms are normal and do not represent serious health or physical risk. Education about *cognitive* symptoms is typically relevant, as well, such as teaching a patient with PTSD that intrusive memories are normal reactions to traumatic experiences, or teaching patients with OCD that intrusive thoughts are common in the general population. Education about the *connection between thoughts and events* may also be relevant during this phase. Patients who have specific beliefs about the connection between thoughts and events need to begin to learn that such connections do not exist. Thought–action fusion (TAF), an OCD-related phenomenon characterized as the belief that thinking about a despicable act is as morally wrong as actually doing it, is one example of the kinds of irrational cognitions that need to be addressed in treatment (36). Behavioral experiments (discussed above) may be helpful when educating about this topic. Psychoeducation may also include identification of past experiences that disprove the patient's dysfunctional beliefs. Finally, once the patient is educated about symptoms, education about the rationale and plan for treatment must occur. Understanding the connection between the cognitive behavioral model of

the symptoms and the rationale for treatment can be particularly important, as it can have an important effect on motivation and follow-through in treatment.

Middle Phase of Treatment

Once assessment and psychoeducation are complete, the middle, and the most active, phase of treatment begins. This phase typically involves ongoing active participation in therapy, as well as homework. Homework often must be completed on a daily basis. Goals and content of therapy sessions during this phase will vary widely depending on the chief complaint. Some general CBT techniques commonly utilized during this phase are discussed later in this section. More information about the active phase of treatment can also be found under the discussion of specific disorders. During the active phase of treatment, significant symptom reduction should occur.

Termination and Relapse Prevention

Once symptoms are substantially reduced, therapist and patient must begin planning for termination. This phase of therapy involves concrete planning in several areas when using CBT. First, programming for generalization and maintenance must be considered, as discussed earlier. Ideally, active phase intervention was planned to target generalization of skills. The schedule of therapy sessions is also often thinned during this time to promote maintenance of therapeutic changes with decreasing therapist support. Finally, relapse prevention must be addressed to ensure that changes endure over time. Relapse prevention strategies may include a cognitive framework for thinking about brief relapses (37,38), such as helping patients to identify antecedents to relapse behaviors and to think about them in ways that do not lead to total loss of treatment gains. Another common relapse prevention strategy is the use of “booster sessions.” Should previous symptoms return or new ones emerge, one or a small number of sessions is often enough to assist the patient in returning to their termination level of functioning.

CBT TECHNIQUES

Cognitive Restructuring

Cognitive strategies are the primary components of CBT interventions (39). Commonly used cognitive strategies focus on restructuring dysfunctional cognitions and intervening on automatic thoughts and their underlying schemas. Automatic thoughts are defined as “cognitions that stream rapidly through an individual’s mind” (13). Such thoughts can be spontaneous or in response to stimuli, a situation, or other

antecedent. Individuals with automatic thoughts typically do not question them for believability. That is, individuals believe that because the thoughts are present they are true or valid. Such thoughts occur with increased intensity and frequency in disorders such as anxiety, depression, and OCD. Automatic thoughts may be valid worries (e.g., about events that have happened or actually could happen) or they may contain cognitive errors or distortions. Common cognitive errors are identified and described in Table 6.2.2.1.

The following cognitive strategies are commonly used to assess and intervene in automatic thoughts and cognitive errors in CBT.

Identifying Automatic Thoughts

Assessment of automatic thoughts does not always rely on interview techniques, especially with children, who may have difficulty understanding and reporting specific thoughts. Techniques such as imagery and role playing can be helpful in identifying automatic thoughts because they set the scene for an event or situation in which specific questions can be asked. For example, when asked to role play a situation, a child can be asked while acting out the scenario what he or she is thinking, feeling, etc. Such exercises are less hypothetical for children, which often help them generate important information that they cannot report during an interview.

Thought recording is another technique that can be used in a similar fashion. This technique is a form of self-monitoring in which events, thoughts, and feelings are recorded on a daily basis. Self-monitoring is a helpful way to assess automatic thoughts, as it does not rely on recollection of thoughts in a specific situation; rather, it requires that the individual record thoughts as they occur or immediately following an event. Although children often require reminders and assistance from adults to keep this type of data on a daily basis, this technique can be developmentally appropriate, as it does not rely on children's memories to assess cognitions.

Socratic Questioning/Examining the Evidence

Socratic questioning is discussed as an important part of CBT, and is one of the main components of cognitive restructuring. This technique involves questioning the patient with the goal of eliciting automatic thoughts and calling their validity into question. During this process, thoughts are considered to be hypotheses, rather than truths, and the patient is taught to determine and evaluate evidence for and against automatic thoughts. This technique is an important way to begin teaching children that thoughts are not true simply because they occur. This technique may be especially helpful with distorted thoughts because rational consideration of evidence increases the patient's awareness that such thoughts are not grounded in reality.

TABLE 6.2.2.1

COMMON COGNITIVE ERRORS TO TARGET IN COGNITIVE RESTRUCTURING

Cognitive Error	Description	Example
Catastrophizing	Placing unrealistic importance on thoughts and events and assuming terrible negative outcomes will occur as a result	“I got a C on my report card, so I will never get into college and I will fail in life.”
Magnifying/minimizing	Placing an inaccurate amount of importance on thoughts, feelings, events (either too much or too little)	Believing getting caught doing drugs is not important because the implications of having a drug problem are too anxiety provoking (minimizing)
Absolutism (black and white thinking)	All events and experiences are thought of in extreme categories, rather than moderately	“I will *never* lose any weight because I just ate a cookie.”
Personalization	Attributing responsibility for external events to the self with no basis for the attribution	“It is my fault that my parents are getting divorced.”
Selective abstraction	Taking information out of context and ignoring relevant details	Thinking “my soccer coach hates me” when the coach did not play the child, even though the child has been played first during the last three games
Arbitrary inference	Making arbitrary conclusions contrary to or without evidence	Believing homework is too hard when in fact the child completed the same work that day in class
Ignoring evidence	Leaving out important information when forming thoughts about events	Believing there is high probability of a home invasion, in spite of the fact that this has never occurred, and all doors in the house are locked
Overgeneralization	Believing the outcome of one situation applies in many situations, when it may not	“All my teachers hate me” when one teacher yelled at the child at school
Attending to negative features of events	Placing greater cognitive importance on negative features of events and ignoring positive features	Focusing on one poor grade when all others were good

Once automatic thoughts have been called into question, the therapist and patient can begin to revise them based on evidence and reality, and can generate new coping thoughts that are more accurate. Examining the evidence can be helpful when combined with self-monitoring because it forces the patient to examine the evidence each time they have a maladaptive thought. This repetition is often helpful in changing a patient’s beliefs over time, as thoughts are constantly being challenged and new coping thoughts can be generated throughout the day.

Correcting Misinterpretations

Socratic questioning may also be helpful in correcting misinterpretations. Individuals

with anxiety and depression, in particular, may misinterpret events, the behavior of others, thoughts, feelings, and other stimuli. Calling into question an individual's interpretation and noting how it impacts thoughts, feelings, and behaviors can be an important aspect of cognitive restructuring, as well.

For example, a client may say, "I had a horrible day, I messed up my class presentation, and everyone thinks I'm stupid." A clinician may respond by asking, "What evidence supports your report? Are you basing your interpretation on your classmates' facial expressions? Did they boo you off the stage? Is it possible there are other explanations for what you saw? Could your classmates have been smiling during your presentation because they wanted to encourage you, rather than to make fun of you? Could someone who looked bored really just be sleepy at the end of a long day? What evidence can you come up with that disproves your interpretation of the events or that people think you are stupid? Weren't you just picked to be the math club captain? How can you, on the one hand, be a leader and, on the other, be stupid?"

Modification of Imagery

Anxious patients, in particular, often have cognitive imagery associated with their symptoms (e.g., imagery associated with a feared or traumatic event). Such patients may benefit from modification of such imagery, such as by identifying aspects of it that are exaggerated. Patients may also benefit from learning to continue the image through to a positive outcome. That is, negative or anxiety-producing images often stop at the height of the crisis in a patient's mind (5), and never come to a positive or adaptive resolution. For example, the images end when the patient has passed out, embarrassed himself in public, or helplessly experienced the traumatic event. Therefore, helping the patient continue the image to a positive resolution (e.g., getting up off the floor after fainting, making statements to others when embarrassed, modifying the outcome of a traumatic event) can be an important exercise in decreasing anxiety and catastrophic thinking. Role-playing exercises may serve a similar role, as they allow the patient an opportunity to understand an event in a new way, with the assistance of a therapist, and then to experience a new, more adaptive, outcome (known as behavioral rehearsal).

Altering Core Beliefs

In addition to identifying automatic thoughts, CBT focuses on the more complex task of identifying the core beliefs, or cognitive schemas, that underlie those thoughts. That is, the thought is typically generated because the individual has an underlying belief about him/herself, which is typically maladaptive. For example, a child who has to complete homework perfectly for fear of being thought stupid may have the

automatic thought, “If I don’t write that sentence with perfect handwriting, everyone will know I am stupid.” Core beliefs that may underlie such a thought could include, “I am stupid” or “Stupid kids are unlovable; therefore, no one loves me.” Understanding these core beliefs is important for relapse prevention in particular, as modification of automatic thoughts will generally be temporary if the underlying belief or schema is not addressed.

Modification of the child’s existing cognitive structures or schemas is an important way to decrease automatic thoughts and cognitive distortions, increase adaptive thoughts, and promote coping (13,29). Through use of many of the cognitive techniques described in the earlier section, therapy must result in a reduction of support for dysfunctional schemas. As such, a primary goal of CBT when addressing thoughts and schemas is the acquisition and use of a coping template through modification of schemas.

It is important to note that identification of underlying cognitive schemas can be a complicated process, which relies on insight, self-awareness, ability to articulate thoughts, and cognitive ability. As such, this level of cognitive intervention is not always appropriate for all ages and ability levels when working with children. Although adolescents can have difficulty articulating themselves, identifying core beliefs may be more successful with this age group than with younger children.

Mindfulness-Based Stress Reduction

Mindfulness is attending to and accepting the present experiences, thoughts, behavior, and feelings without engaging in judgmental thoughts about them (40,41). Mindfulness-Based Stress Reduction (MBSR) (42) was developed to teach people how to practice mindful presence with an accepting, nonjudgmental manner in all areas of their lives (43). MBSR has been shown to improve a variety of psychiatric conditions in adults with a moderate effect size (44). MBSR has been adapted for adolescent populations in a group therapy format (MBSR-T) (45), and has been shown to effectively reduce anxiety, depression, somatization, and obsessive compulsive symptoms, as well as improve self-esteem and interpersonal sensitivity (46). MBSR-T involves skills in attending to somatic states (body scan), learning meditation skills and practicing those skills across a variety of tasks (homework, walking, eating), and practicing yoga (45).

Mindfulness-Based Cognitive Therapy (MBCT) (47,48) uses elements of MBSR, but the focus is on the reduction of maladaptive behavioral and cognitive patterns that are common in individuals with depressive disorders and has been shown to reduce symptoms in chronically depressed patients (49). Research has shown that MBCT improves symptoms of attention and externalizing and internalizing problems in adolescents with externalizing problems (50), and symptoms of inattention, conduct problems, peer relations, and parenting stress in adolescents with ADHD (51).

MBCT has also improved attention, hyperactivity, parenting stress, and mindfulness practice for elementary age children with ADHD (52).

Dialectical Behavior Therapy

Dialectical behavior therapy (DBT) was developed by Dr. Marsha Linehan in the 1970s to treat chronically suicidal adults with borderline personality disorder (53). DBT is delivered in individual and group therapy settings with goals of improving interpersonal effectiveness, developing emotion regulation skills, learning distress tolerance techniques, and using mindfulness strategies to learn to accept intense emotions and feelings. DBT has been modified for use with adolescents to treat depression, suicidal behavior and self-harm, and emotion dysregulation (54–56). DBT with teens includes developmentally and cognitively appropriate modifications to the core elements of DBT, with the additions of caregiver skills training and a family-based module (Walking the Middle Path) to help teens and parents see each others' views, and to learn to effectively validate, negotiate, and compromise (56). DBT targets emotions and behaviors that occur in many psychological conditions and has been found to be effective in the treatment of adolescents with suicidal and nonsuicidal self-injury, eating disorders, bipolar disorder, externalizing disorders, substance use, and PTSD (55,57–59). A universal, school-based DBT program has also been developed for improving social–emotional skills for middle and high school students (60).

Physiologic Techniques

CBT also relies on many physiologic techniques for modifying thoughts, feelings, and behavior. These techniques are particularly useful when treating anxiety disorders, as a core component of such disorders can be misinterpreting and catastrophizing physical symptoms and bodily sensations. These techniques can also be particularly useful with children, as they do not rely on cognitive ability to the same extent as cognitive techniques. Regulated breathing, relaxation training, and interoceptive exposure are all examples of physiologic techniques used in CBT.

Regulated Breathing

Breathing control exercises are often taught in CBT, especially in the treatment of anxiety. These exercises are helpful in two ways. First, they are physically effective for counteracting hyperventilation, reducing physical tension, and decreasing physical sensations associated with anxiety. Second, uncovering the patient's understanding of the physiology behind them is helpful in decreasing their fears of bodily sensations. This change in perception thereby interrupts the vicious cycle in

which patients believe that physical symptoms are a sign of danger, thus increasing anxiety. Although understanding how to physically interrupt this cycle may be beyond the cognitive capacity of young children, learning regulated breathing is nonetheless effective without this understanding. Regulated breathing is most effective when practiced during low-stress circumstances on a regular basis to acquire the skill. This technique can then be applied to increasingly stressful situations.

Relaxation Training

Relaxation training is another commonly taught physiologic technique in CBT. This technique incorporates regulated breathing, but also involves progressively tensing and relaxing individual muscle groups in the body until the entire body is relaxed. When doing muscle relaxation with children, it may be necessary to focus on large muscle groups (arms, stomach, legs, whole body at once) such that the progression does not take too long and to ensure that children have adequate muscle control (it may be difficult for children to isolate small muscles). It has been suggested that this technique is helpful for treatment of insomnia (61). Relaxation training is also often incorporated into anger management treatment protocols (62,63), so that children may learn physiologic techniques for calming down. The goal of relaxation in this context is to reduce disruptive behaviors that accompany anger, especially in impulsive children.

Interoceptive Exposure

Interoception refers to the ability to sense physiologic body signals. With interoceptive exposure, individuals purposefully induce and practice experiencing simulated somatic symptoms such as increased heart rate, breathlessness, and lightheadedness. Interoceptive exposure aims to desensitize patients to these body sensations and to decrease catastrophic beliefs about physiologic arousal, as the patient experiences these sensations without having a feared outcome (e.g., if my legs fatigue I will collapse and blackout in front of this crowd). This technique is most commonly used for panic symptoms, phobias, and OCD.

Behavioral Experiments

Many different types of behavioral experiments may be helpful when using CBT, especially during the psychoeducation phase. These “experiments” are exercises that a patient can complete in session, which demonstrate errors in thinking in a concrete manner.

For example, patients are often taught during psychoeducation that attempts at thought suppression actually lead to increased thinking about distressing topics. To demonstrate this principle, the patient may be asked to engage in an exercise where

he or she is told to not think of a specific topic (e.g., pink elephants) for a period of 2 minutes. Inevitably, patients find during such an exercise that, in fact, they were unable to avoid thinking about the forbidden topic no matter what it was. This behavioral thought experiment allows patients to learn that an increase in the frequency of a thought is a typical consequence of thought suppression. Instead of trying to suppress thoughts, patients are encouraged to observe their thoughts as they "come and go" without trying to suppress them. This technique typically results in a reduction in intrusive thoughts.

Exposure Techniques

Exposure therapy is based on the premise that patients with anxiety symptoms engage in avoidance or "safety behaviors" that do not allow them to experience that their fears will not be realized if they put themselves in feared situations (64). As such, exposure involves developing a progressive hierarchy of feared situations. The patient then engages in a graded series of exercises whereby these situations are experienced or recreated in order to trigger an increase in fear or anxiety sufficient to facilitate subsequent inhibition of the conditioned fear in response to the triggering stimulus or situation. Anxiety typically decreases during exposure exercises, as the patient has the experience that the feared outcome will not occur (e.g., if I think about death, it will not actually cause someone to die). Although historically, repeated exposure to fear triggers was thought to completely extinguish anxiety through the process of habituation, this is not typically the case. Although a significant reduction in fear and anxiety is common, more recent conceptualizations of exposure also emphasize enhancing patients' ability to tolerate or manage their fear and resist the avoidance behaviors most associated with functional interference and distress (65).

Cognitive techniques can also be used to enhance exposure, although care must be taken to avoid inadvertently reducing anxious arousal during the actual exposure trial. For example, rather than just practicing putting oneself in a feared situation and experiencing that the worst does not happen, thus resulting in a decrease of anxiety over time, this exercise might also include specific discussion of what the patient *thought* would happen, whether it actually did happen, reasons for the outcome, etc. With children, this cognitive component may be more difficult depending on developmental level. Exposure therapy is still effective, however, as anxiety reactions extinguish over time with repeated exercises even without this level of insight.

Exposure techniques are often used in treatment of fears and phobias and research supports their efficacy (66). For example, children with specific phobias can be gradually and systematically exposed to situations that increasingly resemble or represent their fear. Over time, they come to realize that the feared outcome does not occur which can lead to reduced fear and/or enhanced fear management abilities.

In the treatment of OCD, the compulsive behaviors are the "safety behaviors" that prevent bad things from happening as a result of the obsessive thoughts. Therefore, exposure exercises in these cases involve having the patient think about or experience their obsessions, which are often urges accompanied by a worry, without engaging in compulsions. This process, termed exposure and response prevention (ERP), facilitates the repeated experience that their feared outcome does not occur (e.g., have the patient experience that if they do not check the door, a robber will not enter the house).

Flooding is similar to exposure, with the exception that it does not utilize a hierarchy, thus, exposure to the target stimuli is not graded and begins by eliciting the full-blown fear response. While flooding may work more quickly than standard exposure, the treatment response is usually less durable. In addition, given the questionable ethics of exposing youth to significantly distressing levels of distress, flooding is no longer recommended or used with children and adolescents.

Exposure can also be used to challenge core beliefs. When used this way, it is known as cognitive response prevention. Cognitive response prevention entails giving the patient homework assignments that involve behaving in a manner inconsistent with the pathologic or problematic belief. This exercise allows the patient a real-life opportunity to cope with thoughts that accompany behavior. For example, a child who thinks, "I am stupid and a terrible student" if homework is not perfect will be assigned to do homework with some imperfections while thinking coping thoughts (e.g., "A couple of mistakes does not make me stupid."). Similarly, an adolescent who must exercise a certain amount of time per day to prevent thoughts such as, "I am fat" will be assigned to exercise for a shorter period of time and see that his or her pants still fit and weight has not changed.

Self-Monitoring/Self-Management

Self-monitoring is an important part of assessing and intervening on automatic thoughts. This technique can be used in other ways, as well, such as to keep track of moods and plan for pleasant events in the treatment of depression, to increase awareness and train competing responses in habit disorders (Tourette disorder, trichotillomania [TTM]), to assess and modify eating and exercise habits in the treatment of eating disorders, and to track use of breathing and relaxation procedures in the treatment of anxiety disorders.

Extending from self-monitoring techniques are interventions in which the child not only self-monitors behavior, but is also responsible for administration of a behavior intervention plan. Such techniques, known as self-management procedures, are also used in the treatment of a variety of disorders (e.g., disruptive behaviors, communication disorders, developmental disabilities, anxiety disorders). These interventions have been successful in improving a variety of skill areas (play skills,

on-task responding, social skills; (67–71)), as well as in decreasing undesirable behaviors (off-task responding, disruptive behaviors, aggression; (69,72,73)).

Activity Scheduling

Activity scheduling is commonly used in the treatment of depression. Models of depression suggest that part of the disorder can be accounted for by a lack of reinforcement in the individual's life (74,75). One cause of this lack of reinforcement is decreased engagement in previously enjoyed activities due to decreased motivation and interest. As such, treatment may include strategies to increase the individual's participation in reinforcing daily activities. In activity scheduling, the patient and therapist agree upon homework assignments to engage in activities that result in pleasurable feelings, feelings of competence/mastery, or other similar positive emotional and cognitive outcomes. Patients begin to monitor their activity and keep daily mood diaries. Using this technique, a change in behavior often results in improvements in emotional functioning.

Applied Behavior Analysis

Applied behavior analysis (ABA) applies operant conditioning techniques to increase desirable behaviors and to decrease undesirable behaviors (76). ABA primarily relies on the use of contingent reinforcement to teach skills (i.e., increase desirable behaviors) and manipulation of antecedents and consequences to decrease challenging (i.e., undesirable) behaviors (e.g., tantrums, noncompliance, avoidance, etc.). In ABA, challenging behaviors are addressed using functional assessment or analysis procedures (76,77) in order to determine the function or "why" of a behavior. Function-based interventions are then developed, which are considered more effective for reducing challenging behaviors than interventions not based on behavioral function (77). Many specific therapeutic techniques that treat a variety of disorders are based on these principles. Several principle techniques specific to ABA therapy are outlined below.

Schedules of Reinforcement

Reinforcement occurs on multiple schedules, which have different impacts on behavior. Schedules of reinforcement are either continuous or intermittent. A continuous schedule is best for initially teaching a new behavior because the behavior is reinforced each time it occurs. Once the behavior is established, it is best to then decrease the ratio of reinforcement to responses (called *thinning* the schedule of reinforcement) so that the individual does not become satiated, leading to decreased motivation. When thinning a continuous schedule of reinforcement, there

are four types of intermittent schedules that can be used. These are (1) fixed interval (the individual is reinforced on a fixed time interval), (2) variable interval (the individual is reinforced after varying time intervals), (3) fixed ratio (the individual is reinforced after a fixed number of responses), and (4) variable ratio (the individual is reinforced after a variable number of responses). The variable ratio schedule is the most effective schedule when trying to maintain a behavior because it creates relatively high steady rates of responding.

Many therapy techniques are associated with the principles of operant conditioning. Some common techniques can be found in Table 6.2.2.2. Therapies that use multiple techniques based on operant conditioning include ABA programs for children with autism and various types of behavior management programs, such as Parent Management Training (PMT) (78,79) and Problem-Solving Skills Training (PSST) (4). These therapies will be discussed in detail elsewhere in this chapter.

Extinction

Extinction occurs when reinforcement that was previously available is withheld in order to decrease or eliminate that behavior. That is, a behavior that was previously followed by positive consequences can be eliminated by withholding those positive consequences. When using extinction as an intervention, it is important to understand the phenomenon of an extinction burst. An extinction burst occurs immediately after removal of previously available reinforcement. When reinforcement is initially removed, the individual will engage in higher, more intense rates of behavior before learning that the behavior no longer results in reinforcement. Once this learning has occurred, the behavior will gradually decrease. Understanding this classically characteristic pattern can be important for intervention, as the initial increase in behavior often leads therapists and patients alike to believe that the intervention is not working. In fact, if the reinforcement is consistently not available during this time, the burst will occur and the behavior will decline.

TABLE 6.2.2.2

COMMON THERAPY TECHNIQUES ASSOCIATED WITH PRINCIPLES OF OPERANT CONDITIONING

Type and Technique	Description
Reinforcement to Increase Behaviors	
Token economy	Reinforcing target behavior with tokens (stickers, points, poker chips) that can then be traded in for reinforcement once multiple tokens have been earned.
Differential reinforcement of incompatible (DRI) or alternative behavior (DRA)	Reinforcement behaviors that are *incompatible* with or serve the same function (*alternative*) as the inappropriate behavior. Best used in conjunction with extinction of inappropriate behavior.
DRO (Differential reinforcement of other	Providing reinforcement for the absence of problem behavior.

behavior)	
Shaping	Reinforcing gradual approximations of a behavior.
Punishment to Decrease Behaviors	
Overcorrection	Applied consequence that involves engaging in a series of retribution steps that are related to the inappropriate behavior (washing soiled clothes after toileting accident).
Response cost	Removal of previously earned reinforcement as consequence of negative behavior. Used especially in conjunction with token economy when tokens are removed.
Time out	Removing all sources of reinforcement for allotted period of time. Typically involves placing the individual in a location where access to reinforcing activities, including social attention, is not available.
Extinction to Decrease Behaviors	Removing previously available reinforcement from an inappropriate behavior to decrease the probability that the behavior will occur in the future.

Counterconditioning

Counterconditioning techniques are used to decrease specific maladaptive behaviors, such as anxiety-related behaviors. Use of such techniques requires pairing a maladaptive behavior with an incompatible behavior in order to eliminate the maladaptive behavior. Counterconditioning techniques are based on the work of Wolpe (80), who stated, “If a response antagonistic to anxiety can be made to occur in the presence of anxiety-evoking stimuli so that it is accompanied by a complete or partial suppression of the anxiety responses, the bond between these stimuli and the anxiety response will be weakened.” For example, in one of the earliest demonstrations of counterconditioning, Jones (81) cured a child’s phobia of a rabbit by systematically exposing the child to the rabbit while pairing the exposures with eating preferred food when the child’s hunger impulse was high. Over time, this conditioning led to a reduction of the fear response to rabbits.

Systematic Desensitization

Systematic desensitization (80) is perhaps the most commonly used counterconditioning technique. It involves training relaxation techniques to be used in conjunction with an anxiety hierarchy for the purpose of reducing fear and anxiety over time. The four stages of systematic desensitization are (1) relaxation training, (2) constructing the anxiety hierarchy, (3) desensitization in imagination, and (4) in vivo desensitization. Specifically, this technique uses an imaginal or in vivo exposure hierarchy paired with progressive muscle relaxation techniques to reduce the anxiety/fear reaction to specific situations. This treatment is typically done first through visualization, followed by in vivo training.

Originally, this technique was based on the premise of counterconditioning; that is, pairing the feared stimulus with relaxation to counter the fear reaction, which

results in decreased anxiety. Evidence suggests, however, that the exposure exercises may be the active ingredient in this treatment (13,82), rather than the counterconditioning.

Systematic desensitization is supported in the literature for use with children; however, studies that demonstrated efficacy typically targeted specific, subclinical fears. Little research has been conducted on its use with more generalized anxiety (29) in children. This technique may have limited use with children under age 9 because younger children often have difficulty understanding the notion of a hierarchy, and they often have problems using visual imagery (29,83).

Aversive Counterconditioning

Aversive counterconditioning is another related technique, based on principles of classical conditioning. This technique pairs the target behavior or stimulus associated with it (conditioned stimulus) with a stimulus (unconditioned) that naturally elicits an unpleasant response. As a result, the maladaptive behavior is increasingly avoided in order to avoid the negative outcome. This technique is most commonly used in the treatment of addictions and problematic sexual fetishes. For example, the use of medications such as disulfiram (Antabuse) that cause an individual to be physically ill when consuming alcohol relies on principles of aversive counterconditioning to reduce the patient’s drinking behavior. While these techniques may be periodically relevant in the treatment of adolescents, they rarely apply to treatment with children.

Covert Sensitization

Covert sensitization relies on the same principles as aversive counterconditioning; however, the individual *imagines* an aversive condition while imagining engaging in maladaptive behavior, rather than actually experiencing the negative stimuli.

Habit Reversal Training

Habit reversal procedures are most commonly used in the treatment of Tourette’s and other tic disorders, as well as hair pulling (e.g., TTM), skin picking disorders, and related body-focused repetitive behaviors (e.g., nail biting) (84). Habit reversal involves three components: (1) Awareness training (e.g., increasing awareness of the urges, sensations, or other phenomena that trigger the target behavior; (2) Competing response (e.g., implementing a behavioral response physically incompatible with the target behavior immediately following the triggering event); and (3) Social support training (e.g., teaching a parent or other responsible individual to monitor and praise correct use of the first two components).

INDICATIONS AND EFFICACY

A wide variety of disorders are commonly treated using cognitive-behavioral treatment strategies. These are outlined in this section with a cognitive-behavioral model of each disorder, followed by a description of the application of CBT to its treatment.

ANXIETY DISORDERS

Cognitive-Behavioral Model

CBT for anxiety "focuses on dysfunctional cognitions and their implications for the child's subsequent thinking and behavior" (4).

Similar to adults, cognitive distortions are thought to play a major role in the development of anxiety in children and have been defined as "information processes that lead to misperceptions of oneself or the environment" (4). The primary cognitive distortion in patients with anxiety disorders is overestimation of the danger associated with certain situations, bodily sensations, or even thoughts (85). Distortions or overestimations may include inaccurate estimates of (1) the likelihood of an event, (2) the severity of an event, or (3) one's coping skills and the availability of help, support, or escape (5). Individuals with anxiety may also tend to interpret events from a negative and, therefore, inaccurate perspective, especially with regard to beliefs about self. For example, an individual with anxiety may have negative thoughts in specific situations when anxious (e.g., kids don't want to play with me because I am stupid, vs. kids don't want to play with me because they all like soccer and I don't).

The two-factor learning theory (86) has been proposed to explain the development and maintenance of fearful behavior. This theory proposes that an anxiety reaction is initially elicited via *classical conditioning* when a feared stimulus or event is experienced. As a result, the individual avoids the situation in the future to avoid experiencing the anxiety again. The avoidance behavior is then reinforced under an *operant conditioning* paradigm when distress is avoided as a result. The individual does not have an opportunity to learn that exposure to the stimuli is unlikely to result in the traumatic outcome again. For example, if a child encounters a scary dog while walking outside, he or she might come to believe that going outside is dangerous (classical conditioning). As a result, staying inside reinforces this notion, as the child does not experience anxiety unless he or she goes outside (operant conditioning). Therefore, until the child can learn that going outside does not result in negative outcomes, the anxiety reaction will continue to be reinforced. Similarly, Clark (5) has proposed that reflexively elicited somatic and cognitive symptoms of anxiety become problematic when they are misinterpreted as indicating danger is present

(I'm going crazy). Such an interpretation can lead to further increased physiologic arousal, which then serves to confirm the initial incorrect hypothesis.

Symptoms of anxiety in children may be physiologic, behavioral, and/or cognitive (29,87). For example, physiologic symptoms may include shaky voice, rigid posture, perspiration, abdominal pain, flushed face, need to urinate, trembling, and increased heart rate. Physiologic symptoms, especially ongoing somatic complaints, are often the most common anxiety symptoms in children, as their cognitions may not be as clear and identifiable as those of adults. Behavioral symptoms may include nail biting, avoidance, thumb sucking, crying, toileting accidents, and others. Cognitions may include thoughts of being hurt or scared, thoughts of danger, self-critical thoughts, preoccupation with evaluation by self and others, worries about likelihood of severe negative consequences, ruminative thoughts, and intrusive images or sounds. These can be difficult to determine in anxious children who may not be accurate reporters or who may not have enough self-awareness to understand their thoughts clearly (88). Distorted information processing is another cognitive area that may be involved in anxiety. For example, distorted/biased views of social or environmental cues, preoccupation with evaluation by self and others, preoccupation with likelihood of negative consequences, or misperception of demands in the environment (29) are common distortions.

Treatment

Treatment strategies for anxiety in children must target cognitive, behavioral, physiologic, and emotional aspects of the disorder. Kazdin (4) suggested that these strategies must "help the child develop new skills, provide new experiences for the child to test dysfunctional as well as adaptive beliefs, and assist the child in processing new experiences." Treatment strategies can be divided into several categories, based on which symptom area they address.

Physiologic Treatment Strategies

In CBT for childhood anxiety, physiologic symptoms are typically targeted first, given the high rate with which these symptoms occur in this age group and the difficulty many young children have in identifying and changing cognitions (25). The most common methods for addressing the physiologic symptoms of anxiety are relaxation training and systematic desensitization. Relaxation training for children typically involves a combination of progressive muscle relaxation, deep breathing, and pleasant imagery, which the child and therapist develop prior to starting the training. In systematic desensitization, relaxation techniques are paired with a fear hierarchy to countercondition the fear response. Studies of efficacy for systematic desensitization have generally shown efficacy with otherwise nonclinical samples

who have specific fears (89). As systematic desensitization requires the child to report levels of anxiety in relation to various stimuli on a hierarchy, it may be difficult for young children (under age 9). Relaxation training, however, has been used with younger children, although they may not acquire the skill as well as older children.

It has been suggested that young children may have more difficulty with systematic desensitization for two reasons. They appear to have difficulty acquiring the skill of muscle relaxation and may not be able to clearly visualize the fear-producing stimuli (90). Therefore, in vivo desensitization may be more effective with younger children (91). Using developmentally appropriate imagery may help remediate this difficulty, however, such as in a case example by Jackson and King (92). In this example, a child was taught to imagine that Batman (a preferred cartoon character for this child) was accompanying him to view the feared stimulus (the dark and shadows). After four sessions, the child no longer evidenced fear of the dark.

Behavioral Treatment Strategies

Children may also benefit from strategies that address learning new behaviors, such as coping skills. For example, modeling has been used to demonstrate desired coping behaviors for use in a feared situation. The child is then reinforced for engaging in these behaviors and can be provided with feedback (93). The therapist is often used as the coping model (94). For example, the therapist can place him/herself in an anxiety-producing situation and model self-talk in front of the patient. In group settings, children may be models for one another, as well. Role-plays have also been used, particularly with younger children who have difficulty describing anxiety-provoking events. The role play itself may allow the therapist to observe when the child becomes anxious and may help facilitate a more in vivo discussion about the child's cognitions at that time (29). Role-plays may also serve an important behavioral rehearsal function, which allows children to practice new skills under less stressful circumstances before being required to use them in the actual anxiety-provoking situation. Children can also be taught problem-solving steps, such as the ones proposed by Spivak and Shure (95). These include (1) problem identification, definition, and formulation; (2) generation of alternative solutions; (3) choosing a new strategy; (4) implementing the new strategy; and (5) evaluating the new strategy. These types of steps are often the foundation for skills training curriculums for children, both in group and individual therapy.

Cognitive Strategies

Children with anxiety disorders often require assistance in identifying their dysfunctional thoughts and beliefs, which they then must learn to modify. Several strategies are suggested for modification of cognitions and the cognitive and

behavioral processes that maintain them. First, psychoeducation is used to increase children's awareness about their cognitive processes and to help them understand how their thoughts maintain anxiety symptoms. An extension of psychoeducation is refocusing the child's attention on less negative aspects of situations, less negative self-evaluation, and less negative interpretations of events. Self-talk is also used to identify maladaptive thoughts (e.g., those that are anxiety-provoking) and internal dialogue, and then to dispute or correct misinterpretations or biases (29,96). For example, children can be taught to think about evidence for and against negative thoughts when they have them. This method of questioning thoughts typically leads the child to the conclusion that the "evidence" does not support their thinking. Similarly, when children have intrusive thoughts, images, or ongoing internal dialogue, they can be taught thought-stopping techniques to interrupt the cycle, such as thinking about yelling, "Stop!" while picturing a large stop sign in their head.

Combined Strategies

Many CBT treatment plans combine physiology, learning new behaviors, and changing cognitions. For example, in vivo exposure and exposure with response prevention combine cognitive and behavioral strategies to reduce anxiety related to specific stimuli or symptoms of OCD. A series of waitlist controlled studies by Kendall et al. (97,98) has demonstrated the efficacy of a combined CBT approach in treating generalized, separation, and social anxiety disorders, with gains maintained up to 7 years posttreatment (98).

OBSESSIVE-COMPULSIVE DISORDER

Cognitive-Behavioral Model

The cognitive-behavioral model of OCD involves "intrusive and distressing thoughts, impulses, or images about possible harm coming to oneself or others" (5), which must then be neutralized through counter-thoughts or behaviors to prevent harm or negative consequences from occurring. Many people have intrusive thoughts of this nature; however, individuals with OCD are thought to interpret them differently. That is, they assume that such thoughts are a sign that something terrible will actually happen and they will be responsible for the outcome. As a result, they engage in all types of neutralizing, undoing, and compensatory behaviors (e.g., checking, washing, ordering, meaningless rituals, self-statements) in order to prevent negative outcomes. As the distressing thoughts in OCD typically have a low likelihood of actually occurring, the individual comes to believe that their neutralizing behaviors (compulsions) successfully prevented the feared outcome. As such, the individual never comes to realize that they are unnecessary. In addition, and perhaps more

importantly, reduction in distress and anxiety contingent on performance of the ritual creates a negative reinforcement cycle, which serves to further strengthen the perceived benefits of the ritual (the so-called OCD cycle) (99).

Treatment

Numerous studies support exposure-based CBT, known as exposure and response prevention (ERP), as an effective and appropriate first-line treatment for pediatric OCD, either alone or in conjunction with medication (100,101). ERP begins with the development of a hierarchy of obsessions and compulsions, listed in order from least to most distressing (Table 6.2.2.3). Once this hierarchy is developed, exposure begins with the least distressing item on the hierarchy. Depending on the nature of the obsession, exposure involves either exposing the individual to the actual stimuli or having him/her imagine or think about it. As the symptom pattern in OCD involves compulsions that are tied to obsessions, the exposure will elicit a desire to perform the compulsion. Thus, it is important that the patient refrain from engaging in their compulsive response (response prevention), or at least delaying the response for a period of time, if treatment is to be successful. Repeated exposure to the anxiety (the obsession) in the absence of the neutralizing response (the compulsion) results in inhibitory learning whereby the child's anxiety response to the exposure target decreases. Although some decrease in anxiety is often observed before moving the patient to the next hierarchy item, increasing the amount of time the child is in a state of heightened arousal is thought to enhance inhibitory learning and to lead to better outcomes.

TABLE 6.2.2.3

SAMPLE OCD SYMPTOM HIERARCHY

OCD Ritual	SUDS Rating
Mom needing to say "okay, goodnight" three times at bedtime	9
Washing hands when feel contaminated	8
Turning light switch on/off three times	7
Turning TV on and off three times	6
Erasing and rewriting math homework	6
Rereading sentences in history book until feels right	5
Rereading sentences in pleasure books until feels right	4
Needing to brush teeth at bedtime three times	3
Saving old school homework	2

SUDS, subjective units of distress scale; SUDS rating, degree of distress associated with not being able to complete each listed ritual.

A better understanding of the inhibitory learning processes underlying exposure has led to recommendations designed to increase the efficacy and durability of the

treatment (102). These recommendations, which focus on enhancing the generalizability of the underlying inhibitory learning, include greater focus on violating expectancies (e.g., having a child who believes he or she can refrain from washing for only 2 minutes stay in the exposure for 3 minutes) and eliminating safety signals (e.g., using multiple therapy settings or removing parent from the room). In addition, once the child has some experience and success with exposures, selecting exposures randomly from the hierarchy and conducting exposures to multiple hierarchy items simultaneously can also potentially lead to more durable treatment gains (103). At times, booster sessions may be required if obsessions begin to provoke anxiety again.

Numerous studies support both individual and group-administered exposure-based CBT as an effective and appropriate first-line treatment for pediatric OCD, either alone or in combination with medication (100,101). The Pediatric OCD Treatment Study (POTS) (104), the largest pediatric trial of CBT for OCD to date, compared CBT alone, selective serotonin reuptake inhibitor (SSRI) alone, and combined CBT + SSRI to pill placebo in a sample of 128 youngsters drawn from three treatment sites. Overall, CBT + SSRI was found to be the most effective treatment, yielding illness remission in 54% of youngsters, followed by CBT alone (39% remission), SSRI alone (21% remission), and placebo (3% remission). At one site, however, CBT alone was found equally efficacious as CBT + SSRI, leading the researchers to conclude that either CBT or CBT + SSRI should be considered the first line of treatment in children with OCD.

Randomized comparative trials have also demonstrated ERP to be more efficacious than relaxation training in both elementary-aged children and teens (105) and younger children (106).

PHOBIAS

Cognitive-Behavioral Model

As noted earlier, the two-factor learning theory (86) has been used to explain the development and maintenance of phobic behavior, in that repeated avoidance of the feared situation or object does not allow for disconfirmation of distorted harm beliefs and, in fact, is reinforced by the patient's belief that such avoidance is keeping him/her safe. As a result, treatment involves breaking this operant conditioning cycle and teaching the individual that the feared situation is unlikely to occur again even when it is not avoided.

Treatment

Several CBT strategies have demonstrated efficacy in the treatment of phobias.

Graded exposure, systematic desensitization, participant modeling, and relaxation training (80,107) have all been effective treatment strategies. Exposure treatment of phobias is much like that described above in the treatment of OCD. In the case of phobias, the individual is exposed to increasingly difficult versions of the feared stimuli, and is prevented from escaping contact with the situation or object. Over time, the individual learns that the feared stimulus or situation does not result in the expected danger, and is, in fact, safe. Long-term treatment success is dependent on the patient retrieving this new learning when they later encounter the fear stimulus. Initially, treatment involves imaginal exposures and then later in vivo exposure exercises.

An intensive form of exposure therapy whereby youth complete one session treatment (OST) has promising outcomes (108). OST utilizes in vivo exposure, cognitive challenges, participant modeling, reinforcement, and psychoeducation (109). An additional promising component for augmenting exposure-based treatment of phobias is the addition of Attention Bias Modification Training (ABMT). ABMT involves using a computerized task to train the patient to quickly shift attention away from threatening stimuli toward a neutral or positive stimuli. This approach has a stronger effect for children with higher threat vigilance (rather than avoidance behavior), as the goal of ABMT is to reduce biases to preferentially attend to fear stimuli, which is thought to maintain anxiety for a subset of anxious children (110,111).

Treatment of social phobia may involve additional components, most notably social skills training (112–114). This combination of CBT with social skills training (called Social Effectiveness Therapy for Children or SET-C) was found to be efficacious for children and adolescents with social phobia (112), with gains maintained at 3-year and 5-year follow-up (113,114). SET-C is a behaviorally oriented intervention where children are taught social skills and coached to complete exposures with nonanxious children. Similarly, Spence et al. (115) found that CBT with strong social skills training, as well as parent involvement in treatment, improved social anxiety symptoms in approximately 80% of youth to the subclinical range, with gains maintained at 12-month follow-up (115). SET-C components have been incorporated into a school-based group treatment called Skills for Academic and Social Success (SASS), with 67% of treatment subjects no longer meeting criteria for social anxiety compared to waitlist controls (116–118). Treatment gains were maintained at 5-year follow-up (119).

Although cognitive-based interventions are not as utilized with children compared to behavior-based intervention, Melfsen et al. (120) demonstrated that cognitive-based intervention with no habituation component for socially anxious youth significantly decreased social anxiety symptoms and negative feelings of self-worth compared to waitlist controls, with 30% of patients no longer meeting criteria for social anxiety. The cognitive-behavioral treatment focusing on cognition involved

"(a) using the child's own thoughts, images, attentional strategies, safety behaviors, and symptoms, (b) systematic manipulation of self-focused attention and safety behaviors, (c) systematic training in externally focused attention, (d) techniques for restructuring distorted self-imagery, and (e) behavioral experiments in which a habituation rationale was not used" (120). Although the percentage of treatment participants who no longer met criteria for social anxiety disorder did not reach the range that is typical for CBT treatments (54%), this cognitive-focused intervention showed promising results (121).

SELECTIVE MUTISM

Cognitive-Behavioral Model

Selective mutism is closely related to social anxiety and it is characterized by persistent failure to speak in public situations where speaking is expected, despite speaking in other situations (122). In recent history, selective mutism was thought to be a manifestation of oppositional behavior (123), but research has shown that selective mutism is related to anxiety, shyness, and social anxiety. Developmental delays, speech articulation, and communication problems are also very common comorbid conditions (124–126). Onset of selective mutism is often at a very young age. When a child does not speak, and, by consequence, they can still function or get their needs met (e.g., an adult speaks for them, another child answers the question, they avoid aversive instructions), the child escapes the demand that is feared (speaking aloud), and, thus, the avoidance behavior is maintained.

Treatment

Selective mutism is typically treated using behavioral methods that begin with a functional assessment to evaluate antecedents of the child's failure to speak and the consequences following the behavior (127,128). Based on the observed patterns, shaping and systematic desensitization with gradual exposure to speaking situations are used to increase the frequency with which the child verbalizes (129–131). Cunningham et al. (131) proposed two types of fading: situational and individual. In situational fading, the child and a person he or she is willing to talk to are gradually and systematically moved from a location where speech occurs to one where it does not. In individual fading, new individuals are gradually and systematically introduced into situations in which the child already speaks. When these systematic shaping procedures are paired with reinforcement of speaking, the child gradually learns to speak to an increasing number of individuals in an increasing number of settings.

Bergman et al. (132) developed a novel behavioral intervention for treatment of selective mutism and functional speech (Integrated Behavior Therapy for Selective

Mutism [IBTSM]) and found increased functional speaking behavior as rated by parents, teachers, and blind independent raters and reduction in social anxiety symptoms as rated by parents (132). Oerbeck et al. (133) developed a home- and school-based cognitive behavioral treatment for selective mutism involving defocused communication (e.g., sitting beside instead of across from a child, creating joint attention by looking at preferred item, wondering aloud rather than directly speaking to the child, accepting speech in neutral manner, and continuing to talk even if the child does not speak) and behavioral techniques of stimulus fading in the clinic setting, followed by the school setting. The study found that the treatment groups had significantly improved speaking ratings compared to baseline, and half of the participants no longer met criteria for selective mutism posttreatment (133). Treatment effects were maintained at 1-year follow-up and were especially robust for the youngest participants (134).

PANIC DISORDER

Cognitive-Behavioral Model

Panic disorder is characterized by a fear of impending disaster, which is confirmed by physiologic and cognitive symptoms. Individuals with panic disorder often misinterpret their symptoms as confirmation that their anxiety represents real danger, which results in more anxiety, leading to further symptoms, and so on. This loss of control over those symptoms leads to further anxiety, which is a maintaining factor in panic attacks. Individuals with panic disorder typically fear having panic attacks in certain situations and begin altering their behavior as a result. For example, in agoraphobia, individuals may resist leaving the house due to anxiety about the social or interpersonal consequences of having an attack in public. The distinguishing factor between panic disorder and other phobias, however, is that the precipitating factor in the attack is a fear of having one, rather than a fear of a specific stimulus. Therefore, in differential diagnosis of these disorders, an individual who has a panic attack in an elevator because he or she does not like small, enclosed spaces would be diagnosed with a specific phobia, whereas an individual who has a panic attack in an elevator and subsequently refuses to use elevators for fear of having an attack there would be diagnosed with panic disorder.

Treatment

Treatment of panic disorder involves cognitive and physiologic strategies, as well as exposure therapy (135). The patient must learn to interpret bodily cues more accurately and often may benefit from learning to place less emphasis on such cues altogether. Understanding the physiology of the cycle is critical, as well, as the

patient can then learn to intervene to decrease physiologic anxiety symptoms. Interoception refers to the ability to sense body signals. Hypervigilance to body sensations and catastrophic beliefs about possibly having somatic sensations are common for individuals with panic. Thus, patients can learn to decrease catastrophic beliefs about physiologic arousal by practicing interoceptive exposure (tolerating somatic sensations). For example, patients can purposely increase their heart rate, induce dizzy sensations, sweat, or simulate feeling out of breath and learn that presence of these sensations do not result in a panic attack (136).

Self-control and relaxation exercises (controlled, deep breathing; muscle relaxation) are important in preventing and controlling panic attacks and their associated symptoms. Cognitive strategies are important, as well, as patients must learn to decrease their exaggerated thinking patterns. Cognitive restructuring, Socratic questioning, and other related strategies are important in decreasing the catastrophizing and ongoing worry that accompany the panic attacks in this disorder. Exposure therapy is often used in the treatment of panic, as well, as the individual has come to avoid certain situations over time due to fear of having an attack. As such, once the individual learns physiologic and cognitive strategies for avoiding and reducing the severity of attacks, he or she may require exposure therapy to learn that previously avoided situations can now be managed. Exposure exercises are conducted on a hierarchy as described above, and, over time, the individual learns that panic attacks will not occur and that situations are therefore no longer to be feared.

Hoffman and Mattis (137) adapted an adult Panic Control Treatment for Adolescents (PCT-A). PTC-A consists of psychoeducation and correcting misinformation about panic attacks, cognitive restructuring, breathing, interoceptive exposures, and graduated exposure to feared stimuli or avoided situations. Pincus et al. (138) later tested PTC-A (also known as Master of Anxiety and Panic for Adolescents: Riding the Wave) compared to self-monitoring waitlist control and found large treatment effects in the reduction of clinician-reported clinical severity to below clinical threshold, as well as decreased self-reported anxiety sensitivity, and general anxiety and depressive symptoms. Gains were maintained at 3-month posttreatment, and an additional reduction in panic symptoms was found at 6-months posttreatment (138).

POSTTRAUMATIC STRESS DISORDER

Cognitive-Behavioral Model

PTSD is diagnosed when a constellation of anxiety-related symptoms manifests after the occurrence of a traumatic event. Many individuals experience symptoms of PTSD after a traumatic event, including intrusive, unwanted distressing thoughts and

memories, avoidance, hypervigilance, and hyperarousal. Individuals who then develop PTSD, however, do not adequately cope with these symptoms, and they persist or worsen as a result. Over time, many other cognitive aspects of anxiety may then manifest in individuals with PTSD. For example, they may begin to misinterpret the recurrent, intrusive thoughts as a sign that something terrible will happen again, as described above in the development of OCD. They may also develop anxiety about their symptoms that perpetuates the anxious state (similar to panic disorder), such as, "I can't control my recurrent memories so I must be going mad." As such, while PTSD has an etiology very different from other anxiety disorders, its treatment is quite similar, as misinterpretation of thoughts, avoidance, and other anxiety symptoms must be addressed.

Trauma reactions may appear somewhat different in very young (under age 6) children (122,139). Scheeringa et al. (139) proposed an alternative set of diagnostic criteria for preschool-aged trauma victims [PTSD-AA] (139). Scheeringa's modifications to the previous DSM-IV criteria focused on behavioral symptoms, rather than on thoughts and emotions, and also provided a developmental lens from which to interpret much of the criteria for young children. PTSD-AA modifications included, (1) the individual does not have to be able to report the anxiety reaction, as many young children are incapable of doing so; (2) recurrent recollection of the event may manifest in repetitive, trauma-related play themes; (3) recurrent distressing dreams do not have to include trauma-related content, but must be distressing; (4) flashbacks may be behavioral in nature, with no accompanying verbal description; (5) diminished interest in significant activities may present as constriction of play; (6) a feeling of detachment or estrangement may manifest as withdrawal; (7) loss of developmental skills may occur; and (8) increased arousal may manifest as tantrums and outbursts.

Most of the PTSD-AA modifications were later incorporated into the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5; 5th ed.) (122). In addition to incorporating nearly all of the PTSD-AA modifications, the DSM-5 removed criterion for "response of fear, helplessness or horror," split the former avoidance/numbing criteria into avoidance and negative alterations in mood, and now only requires one symptom in this avoidance criterion for young children instead of three. Furthermore, two symptoms were removed under avoidance criterion, including (1) sense of foreshortened future and (2) inability to recall aspects of the event, and the increased frequency of negative emotional states was added. Finally, the DSM-5 clarified that avoidance of people, conversations, and interpersonal situations may also be present for young children. Evidence suggests that the new DSM-5 criteria for young children are now more diagnostically sensitive (140).

Treatment

Research suggests that CBT approaches are the most effective treatment for PTSD in children (141–147). Exposure is the primary focus in treatment of PTSD (146,148), although other CBT strategies, such as cognitive restructuring and relaxation, are also often used (146,149–151). The literature proposes that the forced thinking about the traumatic incident involved in imaginal exposure may be especially important because studies have shown that avoidance of thoughts associated with the traumatic event is predictive of persisting PTSD (5,152–154).

Studies using CBT to treat PTSD in children and adolescents are somewhat limited; however, several controlled studies have demonstrated clinically significant reductions in symptoms (142,155–158). Additional randomized controlled trials (RCTs) are available for specific populations, such as victims of sexual abuse (159–161).

Trauma-focused cognitive-behavioral therapy (TF-CBT), which is based on the basic principles of CBT, has been shown to be effective in reducing PTSD symptoms in children exposed to trauma (148,162,163), as well as comorbid depressive and internalizing symptoms, with treatment gains maintained at 1 to 2 years posttreatment (162,164). TF-CBT actively involves both parents and children, and includes psychoeducation; the development of relaxation, affective regulation, and coping skills; the creation of a trauma narrative (TN); and parent–child treatment sessions (162,165,166). Gradual exposure to trauma reminders takes place throughout treatment (148).

The formation of the TN is a key component of TF-CBT. Over the course of treatment, children develop a narrative of the traumatic experience by describing the event in detail and by sharing their "thoughts, feelings, and physiologic reactions" (148).

Exposure therapy in the treatment of PTSD is well validated with adults and is also used with children. Exposure therapy in PTSD typically involves repeated, imaginal re-experiencing of the traumatic event until the anxiety associated with these exposure exercises diminishes. Therapists coaching their patients through exposure exercises typically try to elicit as much detail as possible about the patient's experience of the event, including thoughts and feelings that were experienced at the time. This level of detail and focus on thoughts and feelings results in decreased anxiety over time (167,168). Alternative exposure strategies are sometimes used with children, such as writing or illustrating a book about the event in gradual, systematic steps (160), or having them experience the event via play. In vivo exposure may also be helpful in situations where it is possible for the client to be exposed to the location of the trauma or other related variables.

Individuals with PTSD may also benefit from anxiety management training (141,146,167,169) or stress inoculation techniques (149,160,170), which may include cognitive restructuring of thoughts about the event, relaxation, positive imagery and self-talk, thought stopping, self-monitoring, and other physiologic

strategies to decrease hyperarousal (151,171). Cognitive restructuring in PTSD involves altering the distorted cognitions that play a role in the development and maintenance of the disorder. For example, young children often experience serious misattributions about the traumatic event, such as self-blame (160). Anxiety management training may also involve application of learned skills in role-plays and in vivo exposure exercises. Research in this area is limited; however, existing studies appear promising (172).

Parent participation in treatment is often important when working with children and adolescents. Pine and Cohen (160) suggest that parents may participate in exposure exercises with their children, and that they may benefit from learning behavior management techniques.

DEPRESSION

Cognitive-Behavioral Model

Seligman (173) noted that depression in children and adolescents lends itself to a cognitive-behavioral intervention model (when developmentally appropriate), as these individuals tend to exhibit high rates of intrusive negative thoughts (e.g., selective ruminations about past unpleasant events, hopelessness about the future, and helplessness about improving their situation). Consistent with Beck's model (74), adolescents have been shown to attribute positive outcomes to external, unstable, and specific factors (174) and to lack self-efficacy with regard to these outcomes. Individuals with depression may also experience cognitive distortions in attributions, self-evaluation, and perception of past and present events (175,176). Similarly, they may engage in overgeneralization, catastrophizing, taking responsibility for negative outcomes, and attending to negative features of events (175,177,178). These distortions can be thought to result from "pathologic information processing" (17,179), which leads to symptoms of depression.

Children with depression often have low self-esteem, low perceived academic competence, and low perceived social competence (180), and may have poor problem-solving skills, especially regarding interpersonal problems (29). Kazdin (4) also noted that depression in children and adolescents is associated with "restricted behavioral repertoires" (limited participation in pleasant activities, few experiences of reinforcement in the environment), thereby lending itself to the behavioral aspects of treatment.

Treatment

CBT has been found to be effective for the treatment of depression in adults across a variety of studies (179,181) and treatment delivery models (individual CBT, CBT in

conjunction with medication, group CBT, marital CBT). Research also shows CBT to be effective in treating depression in adolescents (182–184). In a study by Clark et al. (182), youth who received brief CBT, in addition to self-selected treatment as usual (e.g., outpatient mental health, antidepressants, school counseling), exhibited significantly better rates of recovery from major depression compared to those adolescents randomized to the treatment-as-usual control condition (182). Another study examining the use of CBT as a continuation-phase treatment after an antidepressant treatment found that those children who received CBT in addition to medication management had a significantly lower risk of relapse, as compared to those individuals in the medication management only group (184).

As symptoms of depression are both cognitive and behavioral in nature, a variety of strategies are employed depending on individual patient symptoms. Cognitive restructuring is often used to address negative thought patterns associated with depression. Socratic questioning, in which the patient examines evidence for and against distorted perceptions, is one strategy for intervening on such thought patterns. Patients may also benefit from self-control strategies, including learning more positive self-consequation (reinforce one's self more, punish one's self less), adaptive self-monitoring (increasing attention to positive actions, events, accomplishments), and more accurate and realistic self-evaluation, such as learning to set less perfectionistic standards for one's self. One kind of adaptive self-monitoring includes monitoring pleasant events and associated moods. This type of procedure encourages the child to engage in reinforcing activities, while simultaneously increasing focus on the resulting positive affective change. Charts such as the one in Figure 6.2.2.1 are easily used with older children and adolescents for this type of intervention.

Skills training is also often involved in the treatment of depression, especially for children and adolescents. Types of skills training may include assertiveness training, conflict management skills training, relaxation training, and social skills training. Social skills training, in particular, may be important for children and adolescents, as poor social relationships are predictive of many psychological and emotional difficulties. Further, interpersonal conflicts with peers are the most common antecedent to adolescent suicide attempts (185). Social skills training involves different components and skill sets depending on the model; however, the focus is generally on teaching skills for initiating and maintaining social interactions (186,187). Social skills interventions may also focus on handling interpersonal conflicts. Other behavioral interventions, such as activity scheduling/monitoring, and tracking pleasant events and associated moods, are also often part of changing behaviors, gaining skills, and increasing self-administered reinforcement.

Pleasant Events and Mood Monitoring							
Name:							
Week of (dates):							
Chart filled out by:							
	Monday	Tuesday	Wednesday	Thursday	Friday	Saturday	Sunday
Pleasant events:							
Mood rating:							
DIRECTIONS: Note pleasant events for each day. Give each day a rating of 0–5 to indicate overall mood for that day. If mood changes significantly within a day, it is fine to give that day two separate ratings. 0 = sad, no energy at all, unmotivated 5 = very happy, nonstop busy, very motivated							

FIGURE 6.2.2.1. Mood monitoring chart for treatment of depression.

The Adolescent Coping with Depression Course (CWD-A) (188–191) is a classroom-based group treatment program for treating adolescents with depression. This program first involves increasing the patient's awareness of negative cognitions, followed by learning new, more constructive ones. Strategies to increase positive reinforcement in the patient's life are then used, such as increasing activities associated with positive reinforcement and teaching social skills associated with increased reinforcement. The final component of the program is parent education, which is designed to facilitate practicing skills learned in session at home with parental support. Ongoing research has demonstrated the efficacy of this model (188,190–193), and further examination of various treatment mediators suggests that a reduction in negative thinking may be the primary mechanism involved in reduction of depressive symptoms (189).

DBT, while originally developed to treat individuals with borderline personality disorder (194), has been shown to be effective in treating other disorders and behaviors, including depression, in both adults and adolescents (57,195,196). For adults, there is an evidence that DBT improves self-reported depression symptoms and promotes remission in patients treated with a combination of medication and

DBT, in comparison to adults only treated with medication (196). DBT also seems to be effective for treatment-resistant depression in adults (195). In a meta-analysis that examined the research on modified DBT with adolescents, posttreatment results indicated that adolescents who had participated in a DBT intervention engaged in less nonsuicidal self-injury and experienced a reduction in depressive symptoms (57). While these findings are encouraging, further research on modified DBT for adolescents is needed.

AUTISM SPECTRUM DISORDER

Cognitive-Behavioral Model

Previously termed "pervasive developmental disorders" in the DSM-IV (197), individuals who meet criteria for any of these disorders (autistic disorder, Asperger's disorder, or pervasive developmental disorder, not otherwise specified [PDD-NOS]) are now diagnosed with autism spectrum disorder (ASD) under DSM-5 (122). ASD is characterized by deficits in social communication skills (i.e., social reciprocity, nonverbal communication behaviors, and age-appropriate peer relationships) and the presence of restricted interests, repetitive behaviors/speech, insistence on sameness, and unusual patterns in sensory processing (122). Individuals with ASD are often conceptualized as having a core disability in social interaction skills and motivation (198). This inherent difficulty in interacting with others, combined with a lack of social motivation, may result in severe learned helplessness over time. The lack of motivation and learned helplessness that children with autism frequently experience requires that alternative methods of motivating learning be used. Therefore, treatment of autism is primarily behavioral and focuses on finding ways to motivate socially appropriate communication, social, and play skills, as well as behavior, to recruit reinforcement that is meaningful to the child.

Treatment

The treatment of ASD involves the use of operant procedures in applied settings, otherwise known as applied behavior analysis (ABA). ABA utilizes operant conditioning procedures (10,11) to target development of functional behaviors that will make a meaningful difference in quality of life for the individual. Behaviors must be observable and measurable, and data on target behaviors must be collected on a regular and ongoing basis in order to evaluate whether observed changes in behavior are the result of treatment implementation. ABA treatment programs are designed to address any developmental domain in which delays are present, including, but not limited to, communication, social, play, cognitive, adaptive, and motor skills. It is also often necessary to focus on the reduction of challenging

behaviors (e.g., tantrums, aggression, self-injury, property destruction), which result from a lack of appropriate skills.

In ABA therapy, the antecedent-behavior-consequence (A-B-C) contingency is used to both teach skills and to reduce challenging behaviors. This framework assumes that antecedents (A) cue or lead to the behavior (B), which is followed by consequences (C) that will either increase or decrease the probability of future behavior. When teaching skills, antecedents and consequences are purposefully introduced in order to create learning trials. For example, an adult might hold a child-preferred object out of reach (antecedent) to cue the child to make a verbal request (behavior), and then reinforce the child's appropriate response (consequence) by providing access to the item. When trying to reduce challenging behaviors, the A-B-C contingency is already in place, as natural factors are typically eliciting (antecedent) and maintaining (consequence) the behavior. As such, these factors must be identified through functional assessment or analysis and altered in order to reduce undesirable behavior.

In ABA therapy, reinforcement is used to teach explicit target behaviors, such as making verbalizations, imitating the actions of others, engaging in appropriate toy play, and following directions. The antecedent-behavior-consequence (A-B-C) contingency is purposefully introduced and manipulated to set up teaching trials to teach skills. Behavioral goals are set for the child at the outset of therapy and progress is tracked through ongoing data collection. Depending on the target behavior, data may be collected using various strategies; however, the most common methods are to collect data on frequency or duration of a behavior. Intensity of a behavior may also be measured, depending on what behavior is being targeted. For example, with severe self-injury, frequency is important, but if the behavior is severely self-injurious, information about the severity of a single incident may also be important. Target behaviors are chosen based on the child's developmental level and current skill set, and are operationally defined for clarity of deciding when reinforcement has been earned and tracking the child's progress.

It is typically recommended that strategies used in the reduction of inappropriate behaviors be selected based on behavioral function. Functional assessment (77) or analysis (76) procedures are used in devising behavior plans for children with autism, as it is necessary to determine the function of the behavior prior to deciding on an intervention plan. Common functions of behavior include behaviors to gain attention, escape/avoid tasks, and obtain tangibles. Once a functional assessment has been completed, interventions can be developed at the antecedent, behavior, or consequence level. Antecedent interventions are typically focused on strategies to prevent the behavior, such as prompts, reminders, and environmental modifications. Replacement behaviors are also taught to ensure the individual is gaining more appropriate skills to meet the same functional need the behavior was serving. Consequence strategies are used to alter how others are responding to the behavior to

ensure inappropriate behavior is not being reinforced. Using functional assessment or analysis ensures that the disruptive behavior will be reduced and a positive replacement behavior will be taught in its place. Behavior plans may include many strategies such as those outlined in Table 6.2.2.2.

There are many types of ABA treatment models, such as discrete trial teaching [DTT] (199), pivotal response training [PRT] (198), and incidental teaching (200,201). Some models are structured and require the child to work one-on-one with a therapist [DTT] (199,202), while others embed behavioral teaching trials into developmentally appropriate interactions in the child's natural environment, such as during play-time, while at school, and within family routines (e.g., PRT) (68,203). Interventions that involve structured one-on-one work between a therapist and the patient (e.g., DTT) are often criticized for limitations in generalization effects. That is, targeted behaviors that are successfully elicited in therapy may not be demonstrated by the child in natural settings. As such, a strong program will address both the need for structured, behavioral teaching interactions to teach certain behaviors, as well as the need for opportunities to promote use of skills across settings, behaviors, and social partners (204). This goal is often achieved through training individuals who regularly interact with the child (parents and teachers) in the use of intervention strategies so that target behaviors may be prompted in a variety of natural settings and interactions. Many specific techniques are used in ABA therapy. Some examples of these are outlined in Table 6.2.2.4.

Recently, there has been increased focus in the literature on treatment models that combine ABA therapy techniques and developmental science (e.g., Naturalistic Developmental Behavioral Interventions [NDBI]; (205)). ASD treatment models, such as the Early Start Denver Model (ESDM; (206)); Joint Attention, Symbolic Play, Engagement and Regulation (JASPER; (207)); and Project IMPACT (Improving Parents As Communication Teachers; (208)), focus on embedding ABA teaching strategies in the natural environment, as well as using developmental methods such as imitation of the child to enhance motivation and use of positive affect to foster shared enjoyment. While many ASD treatment models have focused on embedding behavioral teaching trials in the natural environment, use of natural reinforcement, and use of incidental teaching methods for some time (e.g., Pivotal Response Treatment), most recently, the field is moving away from the focus on individual treatment models and toward the identification of core components that are considered effective in teaching children with ASD (205). Many of these models include or are solely focused on training parents to deliver parent-mediated interventions (208).

Behavioral treatments for children with autism have substantial empirical support (199,204). In one of the earliest intervention studies, Lovaas (199) provided intensive behavioral programming to young children with autism, including the use of operant techniques in a one-on-one therapy setting as well as across individuals

(parents, teachers). After 2 years of intensive (40 hours per week) therapy, the children had made substantial gains, including improvements in IQ and less restrictive school placements, such as mainstream classrooms. Other studies have suggested that 40 hours of one-on-one therapy is not necessary; rather, children can be taught throughout the natural course of their day (68,203,205) by embedding behavioral trials in natural interactions. Whatever the format for teaching, research clearly supports that behavioral strategies are most effective for teaching children with autism.

Several large-scale projects have attempted to conduct exhaustive reviews of the literature and to categorize treatments according to efficacy criteria. For example, the National Standards Project ((209); nationalautismcenter.org) conducted a literature review based on specific criteria, and classified treatments as "Established," "Emerging," or "Unestablished," based on previously developed criteria. Interventions falling into the "Established" category are primarily behavioral or cognitive-behavioral in nature, as are many in the "Emerging" category. Few, if any, in the "Unestablished" category are behavioral or cognitive-behavioral. As the body of literature in this area continues to grow, increasing emphasis is being placed on the use of RCT to demonstrate efficacy of behavioral interventions in autism. While these are still limited in the literature, they are becoming more commonplace, with recent trials supporting ESDM (206), PRT (210), and JASPER (207). As RCTs have been slow to emerge, the field continues to rely on 25+ years of single-case and uncontrolled designs, which demonstrate efficacy of behavioral interventions, especially those that are delivered through early intensive behavioral intervention (EIBI; (211,212)) models.

TABLE 6.2.2.4

ABA TECHNIQUES USED IN INTERVENTION FOR CHILDREN WITH AUTISM

Technique	Description	Example
Providing a cue	Providing the child with an indication that a target behavior is expected	Holding up an item and waiting expectantly for the child to request it
Prompting	Providing the child with the assistance that is needed to complete a desired behavior	Providing a model of the word he or she is expected to use to request an item if the child does not say the word spontaneously
Fading	Making prompts less explicit over time, such that the child more independently engages in a behavior	Move from verbally modeling words to waiting for the child to initiate language independently
Shaping	Providing reinforcement for successive approximations of a target behavior, rather than initially expecting the child to perform the behavior fully	Providing reinforcement for saying, "ba" in reference to a ball and reinforcing better approximations of the word over time until the child can say "ball"
Task analysis	Breaking a complex task down into its simpler parts and	Teaching getting dressed by reinforcing the child after each step (e.g., after putting on a shirt, after

	reinforcing the child for correctly performing each step individually	putting on pants, etc.)
Backward chaining	Teaching a complex behavior by starting with reinforcement for correct performance of the last step and working successively backward to the beginning until the child is being reinforced for performing the whole behavior	Teaching putting on your coat by first reinforcing the child for zipping the coat (the final step in the process) while helping with the preceding steps, then requiring the child to pull the coat onto his shoulders, then requiring him to put his arms in the sleeves, then requiring him to complete the sequence from the beginning without help

DISRUPTIVE BEHAVIOR

Children with externalizing problems can present with a range of disruptive behaviors including noncompliance, tantrums, verbal aggression, or more serious behaviors like physical aggression, property destruction, stealing, or other antisocial behaviors (213). Children with externalizing disorders such as conduct disorder and oppositional defiant disorder are at risk for dropping out of school, adult disruptive behaviors, trouble with the law, antisocial personality, anxiety and mood disorders, substance use, interpersonal problems, marital disruption, and poor physical health (214–216).

Cognitive-Behavioral Model

A cognitive-behavioral model of conduct problems suggests that disruptive behavior develops and is maintained by maladaptive parent–child interactions, specifically those that are coercive (217). Coercive interactions involve the child engaging in disruptive behavior and the parent reinforcing it via inadequate and misguided discipline practices.

Distortions or deficiencies in cognitive processes are often present in individuals with behavioral and conduct problems (4). It has also been suggested that cognitive problem-solving skills play a specific role in the prediction of social and behavioral adjustment (4). Other experts in this area (218–221) have suggested that a variety of cognitive distortions may contribute to risk of conduct problems. Milich and Dodge's (219) information processing model suggests that aggressive children make cognitive and attributional errors in processing information related to interactions with others. Specifically, they recall high rates of hostile cues present in social stimuli (218,219), are prone to attribute ambiguous behavior to hostile intentions (218,220), and ignore some cues in their interpretation of the behavior of others (221). These children also have distorted perceptions of their own behavior, such as perceiving their level of aggression as less than it is and taking less responsibility for conflict than other children (222). Similarly, other models have suggested that children with conduct problems have different outcome expectations and social goals than other children.

Specifically, they may expect that aggressive solutions will decrease aversive reactions/behaviors of others and believe that aggressive solutions will result in positive outcomes (223). Adolescents have been shown to believe aggression will increase their self-esteem, decrease negative images, and will not cause suffering in victims (224). Finally, children with conduct problems often value the social goals of dominance and revenge more than affiliation (225). As a result, they tend toward action-oriented and aggressive, rather than verbal, solutions to social problems (226–228).

Treatment

Cognitive-behavioral interventions with aggressive children are indicated to address attributional processes, problem-solving, schemas for social goals, and expectations regarding the outcome of behavior. Further, behavioral contingencies are often used to motivate use of adaptive, rather than maladaptive skills once alternative strategies have been taught. CBTs have been shown by several meta-analytic studies to effectively reduce externalizing behavior problems for children and adolescents with moderate to large effect sizes depending on initial problem severity and age of the target child (229,230).

It has been suggested that four types of therapeutic changes are required in the treatment of conduct and related disorders (231). These are (1) ecologic, (2) operant methods, (3) medication, and (4) behavioral parent training (BPT). Specifically, ecologic changes include manipulation of environments to reduce antecedents and increase opportunities for learning more appropriate and adaptive behaviors. Operant methods include reinforcing appropriate behaviors across settings, such as home and school. Medication has been suggested as a helpful addition to behavioral programming and other interventions (232,233). Clinicians are cautioned, however, against using medication alone without engaging in a detailed analysis and behavioral treatment of the child's behavior problems. Finally, BPT (sometimes called PMT; (78,79)) is designed to decrease negative and increase positive interactions between parents and children. It also teaches parents behavior management and problem-solving techniques to improve skills in managing behaviors. BPT is considered more effective than any other treatment approach for disrupting the maladaptive parent–child interactions that lead to and maintain child disruptive behavior (234) and has a larger effect size (in the moderate range) than child-focused or school- or community-based interventions (235).

Components of intervention that are typically included in CBT-based programs for reducing externalizing behavior problems include self-monitoring, affect-labeling or emotion awareness, perspective-taking, social problem-solving, relaxation, anger management, and goal-setting (225,236). Self-monitoring, affect-labeling, or emotion awareness training is taught to monitor arousal state, to learn to label the

accompanying emotions, and to learn to recognize trigger situations. Self-instruction includes learning to use inhibitory self-talk (e.g., “Stop and think!”). Perspective-taking involves increasing awareness of nonhostile cues in social situations and teaching children to find alternate explanations for the behaviors of others besides negative ones. In social problem-solving, children are taught to identify a problem and then a variety of choices for responding (such as compromising or yelling) and the associated consequences before choosing a response that will have a favorable outcome. Anger management includes becoming aware when anger levels are rising and to manage it early using relaxation, diverting attention, and coping self-talk. Skills training often involves practice of these alternatives to promote competent enactment when real situations arise. These skills are often most helpful when children learn to “insert” them between the antecedent and the impulsive behavior. In this way, they become preventative and are effective positive coping strategies. Goal-setting is used to establish short- and long-term goals that will help improve functioning (e.g., use calm body during circle time) and is best used in conjunction with an associated rewards system (225,228,236).

Several BPT programs have been developed to target decreasing disruptive behavior. Examples of programs that incorporate the principles outlined above include the Anger Coping Program and Coping Power Program (237–239), Incredible Years (IY) (240), PSST (241), and others (236). Many programs are based on one of two research groups based in the United States: Constance Hanf (Oregon Health Sciences University) and Gerald Patterson (Oregon Social Learning Center) (242,243). Hanf-model BPT programs include Parent-Child Interaction Therapy (PCIT) (244), IY (240), Helping the Noncompliant Child (HNC; (245)), Barkley’s Defiant Children (246) and, later, Defiant Teens (247,248).

PCIT (244) is based on Baumrind’s (249) developmental theory of parenting and social learning theory whereby parents are taught authoritarian parenting style through direct coaching while interacting with their child. PCIT aims to enhance the parent–child relationship while using social attention, limit-setting, and enhancing communication. IY (250) is a cognitive behavioral intervention for young children, ages 3 to 8, focusing on problem-solving and social skills for children. IY includes both parent management and teacher behavior management skills. It has been shown to reduce problem behavior and conduct problems with parents, and to increase self-regulation, social competence, and compliance. It has also been shown to increase parent positive affect and to replace harsh discipline techniques with effective limit-setting and to improve family communication and monitoring (240).

HNC (245) involves two clinician-coached phases: teaching parents to provide differential attention (ignore negative behavior and provide attention and social praise to appropriate behavior), and then compliance training (provide instruction, then praise for compliance or setting limits for noncompliance). Adjunctive interventions can be added including teaching parents self-control (including

monitoring their adherence to HNC techniques), teaching parents about social learning theory, family-related factors including parent support and relationships, and a self-administered version that includes audio and videotapes (245). Defiant Children (246) teaches parents similar strategies to those used in HNC. Barkley later adapted these intervention principles for adolescents in his Defiant Teens program (247).

Kazdin's PMT (78,79) is a widely used model based on Patterson's (217) coercive model of parent–child interactions. The goal of PMT is to alter the interaction patterns between the child and parent, such that "prosocial, rather than coercive, behavior is directly reinforced and supported within the family" (4). Specific parent behaviors that are shaped in sessions over time include (1) establishing clear rules for the child to follow, (2) providing positive reinforcement for appropriate behavior, (3) implementing mild punishments to deter inappropriate behavior, and (4) negotiating compromises. These skills are shaped in treatment sessions through practice, feedback, role-plays, and review of in-home implementation with parents on a regular basis. Intervention also sometimes includes coordination with teachers and other service providers. Parent Management Training-Oregon Model (PMTO) (251,252) is a similar manualized clinic-based parent training program based on social interaction learning theory that involves replacing coercive parenting practices with effective parenting practices. It has shown efficacy with a variety of populations including children of divorced mothers (253), and chronically offending youth (254).

Other CBT-based treatments that have been found effective for the treatment of disruptive behavior include Positive Parenting Program (Triple P; (255)). Triple P targets prevention of behavior and emotional problems of elementary children in the general population, offers advice or brief therapy for parents of children with mild disruptive behavior, and includes intensive programming or enhanced intensive programming for parents of children with more severe behavior problems (255).

PSST (4,241) is an approach designed to develop interpersonal cognitive problem-solving skills in children with conduct problems. PSST begins with a focus on understanding the thought processes involved in how the child approaches situations. Patients are then taught step-by-step processes that guide them through solving interpersonal problems. The PSST therapist plays an active role in modeling behaviors, cueing and prompting skills, giving feedback, and praising and reinforcing correct use of skills.

Problem-Solving Communication Training is a behavioral family-systems model of parent–adolescent conflict (PSCT; (256)) where parents are taught how to understand and respond to developmental changes that their adolescents experience during puberty, with the goal of reducing adolescent–parent maladaptive interaction patterns and increasing effective problem-solving skills. Studies have shown that when comparing PSCT to PSCT plus BMT, both treatments show a decrease in

parent–child conflicts with no difference between groups (257).

A primarily cognitive-based approach to reducing oppositional behavior involves reframing parents' cognitive explanations for oppositional and disruptive behavior (Collaborative Problem Solving [CPS]) (258). CPS encourages parents to view their child's disruptive behavior as a cognitive skill deficit, rather than as willful disobedience, and teaches parents how to solve problems in a collaborative way while showing empathy, defining the problem from the child's viewpoint, and inviting the child to help solve the problem (258–260). Compared to Barkley's parent training, CPS treatment resulted in equivalent improvement or better outcomes, such as lower rates of ODD symptoms and higher clinician ratings of improvement than parent training alone (259,261).

ATTENTION-DEFICIT HYPERACTIVITY DISORDER

Cognitive-Behavioral Model

In addition to the inattentive, hyperactive, and impulsive symptoms that characterize the various forms of this disorder, children with ADHD have poor self-monitoring and self-evaluation skills, may have difficulty with receptive and expressive language, and suffer from associated executive functioning deficits, such as disorganization, poor problem-solving skills, and difficulty utilizing the appropriate behavior at the correct time. The symptoms of inattention, hyperactivity, and impulsivity associated with ADHD require that patients learn self-control strategies to improve functioning. These self-control strategies typically target cognitions that accompany behavior, as well as the behaviors themselves.

Treatment

Treatment with stimulant medications is the most well-supported and commonly used intervention for ADHD. Stimulant medication shows significant benefits for improving core symptoms of ADHD, as well as secondary improvements in academic performance, and family and peer relationships (262). Risk of developing comorbid psychiatric conditions is also decreased with stimulant treatment (262). Studies show, however, that side effects may not be tolerated or acceptable (263). In addition, previous symptoms of inattention, hyperactivity, and impulsivity typically return to premorbid levels when medication is terminated (264,265). A recent meta-analysis of between-group effects of behavioral treatments for ADHD implemented in the home, school, or peer setting revealed a comparable or greater effect size (Cohen's d = 0.74, approaching the large effect size range) than previous studies have shown (266). Regarding timing of treatment approaches, the addition of stimulant medication after completion of a group parent-training intervention has

been shown to result in fewer classroom rule-breaking behaviors and better therapy attendance, as well as lower cost, than starting with a medication-only regimen and adding behavioral treatment (267). Therefore, combination pharmacologic and behavioral treatments are considered more desirable in the treatment of this disorder (268,269), especially when potential side effects associated with long-term stimulant use are considered (265).

Behavioral or cognitive behavioral interventions in the treatment of ADHD are warranted, and have demonstrated efficacy in increasing learning, improving academic performance, reducing impulsivity, and improving attention and concentration. As criteria for ADHD diagnosis require pervasive symptoms across settings, it is generally accepted that the most effective way to implement CBT in treating ADHD is to program in the home and school, as well as through direct intervention with the individual child (268). Meta-analytic studies have supported BPT, school-based classroom management, and behavioral-based peer interventions (especially in the context of recreational summer programs; (270–272)) as effective psychosocial treatments for symptoms of ADHD (272–274). There is some variability in findings, however, with some meta-analyses not demonstrating support for parent behavioral training as a method for clearly reducing ADHD behaviors, although they did result in improvements in parent confidence and stress, and general child behavior (275). Newer research also supports organization training as an evidence-based treatment for ADHD (274,276,277).

Programming at home involves parent education, which typically consists of psychoeducation around symptoms of ADHD, behavioral observation and measurement, and behavior management skills (269). Parents are first taught to observe and measure behavior, including basic functional assessment skills. They are also often required to increase awareness of their own parenting behaviors during this time, through exercises such as monitoring statements made to their child during a 15-minute period, or being required to practice making only positive statements to their child for a specified time period. Behavior management skills are taught to reward appropriate behavior and to extinguish inappropriate behavior. Specifically, parents learn to use positive reinforcement to increase appropriate behaviors (independent play, compliance, prosocial interactions) and mild punishment to decrease negative behaviors (time out, response cost). Recent adaptations to BPT techniques have included shorting intervention periods, phone-only intervention (278), treatment enhancement, including having single mothers observe clinicians implementing behavior management and incentives (Strategies to Enhance Positive Parent Training [STEPP] (279)), or specifically attracting fathers (e.g., Coaching Our Acting-out Children: Heightening Essential Skills [COACHES] (280)). Parent Friendship Coaching targets improvement of social skills by having parents impose contingencies in the context of playdates to improve social skills (281).

School intervention emphasizes behavior management, as well as additional

techniques specific to school settings. The use of a daily report card, or other daily management system, in which current goals are evaluated is a recommended component of school-based interventions (268). The daily report card facilitates communication between home and school and allows the child to be reinforced at home for good days at school. Environmental and curricular modifications, such as preferential seating in the classroom and shortened assignments, are also often made for children with ADHD. Coordination of goals across contexts (home, school, other activities) is extremely important to ensure consistency of approach. School-based intervention has also expanded to include behavioral classroom management techniques in the special education setting (282). In addition, social acceptance has been targeted using behavioral classroom management with the addition of teacher-delivered praise, attention, and messages of acceptance (Making Socially Accepting Inclusive Classrooms [MOSAIC] (281)).

A long-term goal in ADHD treatment is to gradually fade the adult control to child-driven self-management. This is one of several key procedures taught to the child individually in ADHD treatment packages. Individuals can learn to self-manage a variety of behaviors such as staying on task, compliance, attention, and suppression of disruptive behaviors. Individuals with ADHD also often need social skills intervention, including instruction in self-evaluation skills and understanding how to choose the appropriate behavior for the context. Hinshaw (268) recommended that these skills be taught in groups so that children may benefit from the inherent social context. They recommend that groups be structured with clear limits and reward systems for appropriate behavior. Further, they suggest that teaching methodologies include discussion of target behaviors and goals, modeling, behavioral rehearsal, rewards for correct performance, and feedback. Structured dyadic behavior therapy (283) is a proposed method of socially mediated behavioral therapy whereby behavioral principles are delivered with the emphasis on the process of instruction, modeling, rehearsal, and feedback to develop self-regulation and behavior management skills in a peer dyad.

Organizational interventions, which typically involve teaching children and adolescents to organize their materials and track assignments have recently shown strong evidence for improving symptoms of ADHD (274) both in the clinic setting (Organization Skills Training [OST] (277)), school (Homework, Organization Planning Skills [HOPS] (276)), and home (Plan My Life; (284)).

It has been suggested that cognitive-behavioral strategies are best for treating impulsivity, specifically (29). Teaching step-by-step problem-solving skills, including learning to anticipate the consequences of actions, is often key in the treatment of this symptom. Problem-solving strategies may be taught in a variety of formats, including coping modeling and role-plays (285). For example, in self-instruction training, children are taught to internalize the steps involved in effective problem-solving (286,287); specifically, they are taught steps such as how to

recognize the problem, reflect on solutions, make a decision, and take action (286).

EATING DISORDERS

Cognitive distortions have been described in the literature as the core psychopathology of eating disorders (288,289), with other symptoms being driven by and secondary to cognitive factors. For example, Bruch (290) noted the "relentless pursuit of thinness" in patients with anorexia, and Russell (291) discussed the bulimic patient's "morbid fear of becoming fat." These patients often judge their self-worth almost solely based on weight and shape, leading to related emotional difficulties, such as low self-esteem, and cognitive distortions, such as perfectionism (especially in anorexia). The cognitive distortions are then thought to underlie all other eating disorder symptoms, such as dieting and compensatory behavior, arbitrary rules imposed upon oneself about eating (e.g., lists of allowed and forbidden foods, times of day that one is allowed to eat), and extreme negative reactions to breaking the rules because of the implications for the patient's dysfunctional belief system (breaking a rule means I have no self-control). Anorexia and bulimia will be discussed separately below, as their cognitive models and treatment differ from one another.

Bulimia

Cognitive-Behavioral Model

In bulimia, the patient is caught in a vicious cycle of bingeing and purging. This cycle originates and is maintained as a result of the mistaken view that compensatory behaviors (vomiting, laxative use, diuretics, over-exercising) are effective means of weight control. This belief causes the barrier against binge eating to be removed and the cycle begins. That is, the individual binges because he or she believes before doing so that there is a means of controlling the outcome. This belief is especially salient with vomiting because it is easier to vomit when the stomach is very full. In this cycle, however, vomiting leads to intense self-hatred, which decreases self-esteem, and exacerbates the notion that weight control will lead to more positive self-evaluation. As a result, the cycle is maintained. This binge–purge cycle is also associated with the antecedent of negative affect, which may lead to overeating and begin the cycle. As a result, cognitive and emotional interpretations of a negative event can significantly exacerbate the bulimic cycle and must be a focus in therapy and relapse prevention.

Treatment

Treatment research for bulimia in children and adolescents is somewhat sparse, with most approaches drawing heavily from the adult literature. The most important issues to address in treatment of this disorder include binge eating and purging behaviors, dieting behaviors, and concerns about shape and weight (288). Motivation for treatment is typically less of a problem in bulimia than in anorexia, as bulimic patients are typically distressed by the binge–purge cycle. While traditional CBT approaches to treat bulimia have been shown to result in a reduction of symptoms, only about 40% of individuals with bulimia recover with traditional CBT treatment, and the relapse rate at follow-up is high (292). Thus, to improve treatment outcomes, enhancements (E) have been made to the standard CBT model, and the new model, CBT-E, has shown greater efficacy (293). In CBT-E, processes maintaining an individual's eating disorder are identified, and that information is used to create a personalized treatment approach (294). Additional modules have also been added to the traditional CBT model that address perfectionism, mood, interpersonal problems, and low self-esteem (295). There are two main forms of CBT-E: the "focused" version (CBT-Ef) and the "broad" version (CBT-Eb). The focused version of CBT-E targets eating disorder psychopathology and is appropriate for most patients (296). The broad approach addresses external obstacles, in addition to eating disorder psychopathology, and should be used with those patients who present with additional maintenance mechanisms (perfectionism, low self-esteem, interpersonal difficulties; (296)).

CBT-E follows four main stages. The main goals of the first stage are "to engage the patient in treatment and change, to derive a personalized formulation (case conceptualization) with the patient, to provide education about treatment and the disorder, and to introduce and implement two important procedures: collaborative "weekly weighing" and "regular eating" (294,296). Self-monitoring of eating and related behaviors is also introduced in this stage and is practiced throughout treatment.

To jointly create the formulation, the therapist and the patient work together to identify the processes that are maintaining the eating disorder, and the patient learns that these mechanisms can be changed. The purpose of the education component is to challenge the patient's misconceptions about body weight and methods of weight control and to inform the patient of the adverse physical and psychological effects of eating disorders. The weekly weigh-in is also used as an opportunity for education, as the therapist helps the patient to understand the number on the scale. Patients are encouraged not to weigh themselves at other times, in order to address excessive body checking.

Establishing a schedule of "regular eating" (planned meals and snacks) is essential in the first stage, as it provides the patient with structure and limits opportunities for binge eating (296). Normalization of the eating pattern typically leads to a reduction in bingeing, which automatically leads to a reduction in purging.

As such, it may not be necessary to separately address purging behavior. Patients agree not to eat outside of this schedule and to not engage in compensatory behaviors (e.g., vomiting, laxatives, diuretics).

The second stage is brief and is considered a transitional stage (294). In this stage, the therapist and the patient review progress; identify any obstacles to change; revise the formulation, as needed; and plan for stage three (296).

Stage three consists of the main treatment. The goal of this stage is to address those mechanisms that are maintaining the disorder. The first step is to help the patient explore the concept of self-evaluation, and attention is drawn to the patient's over-evaluation of shape and weight. The therapist helps the patient to see how other aspects of life are neglected when their priority is their shape and weight, with the goal being to increase the importance of other aspects of life and to decrease the importance of shape and weight (294).

The patient's reliance on dietary rules is also addressed in this stage. The therapist helps the patient to identify the beliefs that are the basis of those rules, and then supports the patient in breaking the rules and challenging their beliefs (296). The goal is for the patient to learn that "the feared consequences that maintain the dietary rule (typically weight gain or binge eating) are not an inevitable result" (296).

In the last stage of CBT-E, the focus is on developing a plan to maintain progress and to reduce the chances of relapse (296).

Preliminary studies suggest that CBT-E can be helpful for younger patients with eating disorders (292,295). Fairburn (294) proposes several guidelines for adapting CBT-E for use with children and adolescents. These include, (1) helping the child/adolescent to develop autonomy and to take personal responsibility, (2) using age-appropriate language and visual aids, (3) assisting the child with social-communication skills to improve peer relationships, (4) involving the school and family in the treatment plan, and (5) intervening early with treatment to mitigate the medical complications associated with eating disorders.

DBT may also be helpful for adolescents with eating disorders since its focus is on improving emotion regulation, which is often an area of challenge for patients with eating disorders (297). Research on DBT for treating adolescent eating disorders is limited to case series (298) and studies with small sample sizes (297), but results suggest that adolescents engaged in a DBT program experience significant reductions in behavioral (e.g., binging/purging) and cognitive symptoms (e.g., over-evaluation of shape and weight, rigidity, guilt) of eating disorders (297,298). Further research is warranted in this area.

Anorexia

Cognitive-Behavioral Model

The primary cognitive distortion in anorexia is that most patients do not believe they have a problem (294); rather, they believe that they are fat and truly need to lose weight. Therefore, the restricting behaviors of a patient with anorexia are reinforced when they result in weight loss. This egosyntonic viewpoint differs from the view of patients with bulimia, who view their bingeing and purging behavior as aversive, leading to negative self-evaluation and motivation to change. The interaction of dysfunctional cognitions and starvation are important maintaining factors in anorexia (288). For example, preoccupation with food and eating exaggerates the concerns about eating, and lowering of mood due to starvation intensifies negative self-evaluation, thus leading to increased efforts to restrict food to control weight. An additional cognitive distortion that may exist involves "an extreme need for self-control upon which shape and weight concerns are superimposed" (288). This notion suggests that cognitive distortions regarding perfectionism, need for control, and rigidity need to be addressed in treatment.

Treatment

Issues that must be addressed in treatment include concerns about shape and weight, dieting behavior, and lack of motivation to change (288). The first goal of anorexia treatment is typically weight gain, especially in severe cases. Since eating disorders share many clinical features, some of the treatment components outlined in the treatment of bulimia may apply; however, several additional components may be necessary to treat anorexia (294,299). Specifically, clinicians treating anorexic patients must address the patient's lack of motivation. Intervention procedures, such as self-monitoring and meal planning, must be introduced slowly, as the patient is likely to resist them initially.

In trying to alter the lack of motivation in anorexia, the patient's viewpoint must be validated, followed by a review of the advantages and disadvantages of the disorder versus change. It may also be helpful to identify clinical features that the patient might view as problematic to increase motivation, which may be accomplished through psychoeducation about the effects of starvation on the patient's health.

Similar to treatment for bulimia, CBT-E has been shown to be a promising treatment for adults and adolescents with anorexia, with some modifications (16,292,299). Treatment for anorexia using a CBT-E approach includes the following stages.

In stage one, the intent is to help the individual realize the need for weight gain and to agree to this as a treatment goal (299). Establishing the therapeutic alliance and engaging the individual in treatment are particularly important in this initial stage, as these patients are typically unmotivated in treatment (299,300). For treatment with adolescents, the therapist works with parents to identify any family factors that may interfere with treatment.

In stage two, individuals work to regain weight to a healthy level, and eating disorder psychopathology is addressed. Weight gain can be facilitated through psychoeducation regarding issues such as starvation, symptoms of the disorder, and the principles of treatment (294,299,300). Eating disorder psychopathology is addressed by targeting the individual's concerns about shape and weight, addressing restrictive eating and dietary rules, helping the individual learn how to self-monitor and to cope with setbacks, and continuing to emphasize weight gain.

In stage three, the focus is on helping the patient maintain their healthy weight and on "ending the treatment well" (294,299), with a focus on helping the patient to accept and appreciate their new body. The therapist and the patient "end well" by creating a personalized plan that identifies any lingering issues and that anticipates potential setbacks to recovery (299). The goal of this plan is to maximize the chances that advances will be maintained and to minimize the risk of relapse (294).

While the use of CBT-E to treat adolescents with anorexia still needs further research, family therapy with a behavioral focus (FT-B) is considered a well-established treatment for anorexia in adolescents (295). In FT-B, parents are considered a resource in treatment, rather than as having caused or maintained the disorder. Like CBT-E, FT-B has three main stages. In the first stage, parents are encouraged to manage their children's weight restoration via interventions such as food exposure, which targets food anxiety and dietary rigidity (301). Once a healthy weight has been reached, families move on to stage two, in which the child or adolescent slowly begins to take control over their eating. Finally, stage three focuses on relapse prevention. The success rate of FT-B in treating adolescents with anorexia is strong: 60% to 90% of adolescents with anorexia who receive a family-based treatment approach maintain recovery or partial recovery at follow-up (292). New research shows that this treatment may be effective in children with restrictive eating disorders under the age of 12 years, as well (301).

TOURETTE SYNDROME

Cognitive-Behavioral Model

Tourette syndrome and other transient tic disorders are characterized by the presence of vocal and/or motor tics. Although often described as involuntary, research suggests that tics are not analogous to other involuntary movements, such as choreas or dystonias (302). Instead, it appears to be the *urge* to engage in the movement that is involuntary, with the movement behavior itself being "irresistible" as a result of the urge. This conceptualization of tics suggests the role of negative reinforcement (dissipation of the urge upon performance of the tic) as a contributing factor in the shaping and maintenance of tic expression (303) and supports the use of cognitive-behavioral treatments aimed at disrupting the urge–tic relationship (304).

Treatment

The treatment literature strongly supports the efficacy of habit reversal training (HRT), alone or in combination with other behavioral techniques for Tourette's and other tic disorders (305). HRT is designed to disrupt the relationship between the premonitory urge and tic expression in analogous fashion to the role of ERP in disrupting the obsession-compulsion relationship in OCD. More recently, HRT has been combined with a functional assessment/intervention (FAI) procedure and manualized as the Comprehensive Behavioral Intervention for Tics (CBIT; (306)). Based on the positive results from a multisite controlled trial (307), CBIT is considered the first-line treatment for youth with tic disorders (308).

CBIT treatment encompasses a number of steps. During the initial assessment phase, problematic tics are identified and are hierarchically ranked according to how bothersome they are. Self-monitoring is then used to provide information regarding tic frequency across different settings, along with serving to enhance child and parent awareness of the tics. During awareness training, the targeted tic is first operationally defined, and the patient is trained to identify the occurrence of each tic and the sensations that precede it. This procedure is completed through several steps including (1) describing the tic and its associated preceding sensations in detail, (2) observing therapist simulations of the tic, and (3) observing and acknowledging one's own simulated or actual tics. These procedures result in a heightened awareness of the tic that is critical for successful implementation of the habit reversal procedures (306).

After awareness training is complete, competing response training, the primary treatment component for habit reversal, is implemented. Competing responses are incompatible behaviors to be performed instead of the tic, contingent on the urge to tic. Competing response training involves determining the competing behavior, clinician demonstration of the competing response, and patient demonstration of the competing response with feedback from the clinician. The clinician continues to provide feedback until it is clear that the patient is performing the competing response correctly (306). Once competing response training for a given tic is implemented in session, the child is instructed to use the competing response as often as possible, and ideally every time, he or she experiences the premonitory urge or other trigger for the targeted tic. It is also important to note that although the urge often reduces in intensity with treatment, complete disappearance is uncommon. As such, HRT may be more accurately characterized to patients and their families as a tool for managing, but not eliminating tics. See Table 6.2.2.5 for sample tic, urge, and competing response form.

Social support training is the final component of HRT and involves having someone else (usually a parent when working with children and adolescents) support the implementation of the procedures outside the session. The role of the support

person involves praising and acknowledging correct use of the competing response, and prompting its use when necessary (when a tic is observed without use of the competing response). The supportive individual should be trained in session through modeling and behavioral rehearsal how to provide both types of feedback. When working with children, it may also be necessary to have a teacher's social support, as the child may spend a substantial period of the day away from parents.

Implemented concurrently with HRT, the FAI procedure is used to identify any environmental variables serving to trigger (antecedents) or maintain (consequences) tics. Although neurologic in origin, multiple studies have demonstrated the sensitivity of tics to environmental factors (309). Therefore, understanding how contextual and socially mediated positive and negative reinforcement play a role in triggering and maintaining tics can be critical to successful treatment. The most common situational antecedents associated with tic exacerbation include playing videogames, home after school, in the car, and doing homework. Tic consequences are classified as either social (e.g., teasing, being told to stop, other negative reaction, positive attention from parent, or other) or escape from responsibility (e.g., leaving the classroom or dinner table, or not having to complete homework or other aversive tasks). Once identified, these variables are addressed using behavioral or other relevant techniques.

TABLE 6.2.2.5

SAMPLE TIC, URGE, AND COMPETING RESPONSE FORM

Name of Tic	Definition	Tic Signals (Premonitory Urge)	Competing Response
Head bobbing	Chin goes down toward the chest and then goes up toward the sky as the top of the head goes back	Tense feelings in neck	Tensing neck muscles gently while facing eyes and head forward
Head turning	Neck jerks or turns side to side repeatedly	Pressure builds in sternocleidomastoid muscle	Hold chin to chest with shoulders gently back
Eye blink	Eyelids open wide and squint repeatedly	Pressure builds around the eye socket	Gently focus on spot a few feet in front while gently/softly closing and then opening eyes
Arm flinch	Arms fly horizontally outward from body or swing back and forth	Deltoid muscle tightens and pressurizes	Hold elbows tight to belt loops with shoulders back
Mouth opening	Jaw opens widely, slight wide eye opening	Pressure builds around the lips	Slight smile with lips closed
Lip pursing/nose scrunch	Lips tightly close and move toward nose; muscle moves nose up and nostrils flare	Pressure builds up slightly on the nasalis muscle and then loosens and reduces muscular resistance on the	Pinch nasalis muscle/upper nose cartilage with medium pressure as to sense

	widely	nose. Urge is to reset.	"pulling nose the long way"
Tongue thrusting	Tongue sticks out through lips	Pressure builds inside tongue itself	Touch tongue to hard palate while gently pursing lips closed

Multiple small studies have demonstrated the efficacy of HRT for Tourette's and other tic disorders in children (304); however, broader acceptance of the behavioral treatment of tic disorders only occurred after publication of the multisite CBIT trial (307). A total of 126 children, ages 9 to 17 years, with Tourette's or chronic tic disorder were randomized to eight sessions over 10 weeks of either CBIT or a manualized version of psychoeducation plus supportive therapy (the most common psychotherapy for youth with pervasive tic disorders at that time). Youth randomized to CBIT had significantly higher response rates (53% vs. 19%) and greater reductions in both tic severity and functional impairment. Treatment gains were largely durable over a 6-month follow-up period. Importantly, the between-group effect size for CBIT (d = 0.68) was relatively similar to those found in similarly designed pharmacologic studies with the important benefit being that, unlike pharmacologic treatments for Tourette's, CBIT treatment was absent significant side effects.

TRICHOTILLOMANIA

Cognitive-Behavioral Model

TTM is characterized by chronic hair pulling, which results in noticeable hair loss, most commonly on the scalp, eyebrows and lashes, facial hair, and pubic hair (310). Hair loss may result in distress and stigmatization that leads to avoidance of social situations. Similar to tic disorders, the individual typically experiences an urge or increasing sense of tension prior to pulling that is released when the behavior occurs (311). TTM is categorized in the DSM-5 under obsessive-compulsive and related disorders (122). The cognitive-behavioral conceptualization of TTM suggests that hair pulling behaviors are maintained by a negative reinforcement paradigm similar to OCD and tic disorders, as tension is reduced when the hair-pulling behavior occurs (311).

Treatment

Unfortunately, the empirical database is quite sparse with regard to the treatment of pediatric TTM; however, the only randomized controlled treatment study in this area provides strong support for the efficacy of HRT (312). In treatment of TTM, awareness training involves becoming aware of the tension or urge that precedes the

pulling, as well as becoming aware of the behavior itself. Awareness training is followed by competing response training and social support, as in tic disorders. The most common competing responses involve engaging the child's hands in a manner incompatible with pulling (e.g., making a fist, squeezing a soft ball, sitting on hands or putting them in one's pocket). HRT is commonly augmented with other treatment techniques including stimulus control, FAI, and anxiety management (313). Stimulus control techniques such as putting bandages on the pulling fingers and/or wearing gloves or other hand coverings enhance awareness of pulling and picking and make these behaviors more difficult. Functional assessment is used to identify settings and other pulling and picking triggers (e.g., sensory, emotional, etc.), as well as maintaining consequences which are then addressed using behavioral or other strategies (e.g., instructing family members to refrain from telling the child to stop pulling). Relaxation training or other anxiety reduction techniques are commonly employed to reduce stress and anxiety, a common symptom trigger (311).

OTHER CLINICAL PROBLEMS

Enuresis

The night alarm has often been cited as the most effective treatment for nocturnal enuresis (314–316). This device electronically signals the child with an alarm when it becomes wet with urine, thereby providing a prompt to create an active avoidance response when the urinary need occurs, to inhibit urination, and to avoid setting off the alarm (317,318). This procedure has been found to be effective 75% to 80% of the time, with relapse rate at 6 months between 15% and 30% (315,319–322). Alarm training is often packaged with adjunctive treatment components. Full Spectrum Home Training (323) combines alarm training with overlearning (having child purposefully drink water before bed to practice avoidance response at night) and has been shown to decrease relapse rate for alarm-only treatments (318). Dry Bed Training (324) augments alarm training with positive practice (practicing being asleep then rapidly waking and going to the bathroom), waking the child during the night to prompt voiding, self-correction (requiring the child to change the bed and their clothes after a toileting accident, appropriate to their developmental level), self-recording successes and failures, and reinforcing the child for successful nighttime toileting behaviors using tangible and social rewards. This combination treatment lasts 4 weeks, with approximately a 40% relapse rate, and is thought to be more effective than the night alarm alone in relapse prevention (321,325–327). Friman and Jones (328) created an optimal treatment plan for nighttime enuresis by combining the urine alarm with adjunctive treatment components.

Children who have diurnal enuresis are often treated behaviorally, whereby they are prompted to use the bathroom on a regular schedule (e.g., once per hour) and are

then reinforced for trying as well as for actually urinating in the toilet (329,330). Over time, prompts can be faded such that the child learns to initiate using the toilet independently. This process may also be accompanied by overcorrection or positive practice. For example, when the child has a toileting accident, he or she may be prompted to return to the scene of the accident and to go through all the steps involved in going to the toilet (e.g., walk to the toilet, pull down pants, sit down, wipe, stand up, etc.) multiple times to practice the positive behavior.

Encopresis

Fecal incontinence often occurs when children become constipated or when there is bowel retention, which can lead to physiologic changes such as decreased ability of the muscle groups to engage in a bowel movement and reduction in the sensation needed to trigger a bowel movement (331). It has been proposed that the pain of having a bowel movement when constipated causes children to become avoidant of doing so due to aversive conditioning and can result in toileting resistance, withholding, and incomplete voiding (231,332,333). Therefore, treatment of encopresis often consists of a combination of laxative prescription, dietary changes, and behavioral methods (334). For example, children are often given laxatives to ensure regular, pain-free bowel movements and are then rewarded for having a movement in the toilet (335–337).

In addition to laxative therapy and dietary changes, behavioral interventions include skills training, establishing a toileting routine, reinforcing the child for sitting on the toilet for a short period of time on a systematic schedule (in the morning, after school, and before bed), and increasing motivation (320). In addition to reinforcement for taking bathroom trips, differential reinforcement can be used if a bowel movement actually occurs. In this way, adaptive toileting behaviors are taught in addition to training actual bowel movements. These procedures may also be complemented with regular pants checks, with clean pants resulting in reinforcement, as well. Overcorrection procedures are sometimes used in conjunction with pants checks, in which the child is required to wash the soiled clothing and to take a bath (337). These procedures must be modified developmentally, as they may result in significant resistance from young children, thereby making the training experience more negative than is necessary. A recent review of behavioral treatments for encopresis with constipation supported behavioral treatments in conjunction with laxative therapy for reducing soiling accidents and author-defined successful resolution of fecal incontinence compared to laxative therapy alone (338).

Stuttering

Direct treatment of stuttering involves working on the speech of the child, while

indirect treatment involves changing elements in the environment. While in the past, there was an attitude that addressing stuttering would make the condition worse, by the 1970s, indirect treatments involving manipulation of the environment around the child prevailed. More recently the focus has shifted to direct treatment of the child with the involvement of the parent. Relaxation training is often cited as the most common treatment for stuttering. Often when children are encouraged to slow down their speaking, to take deep breaths, and to relax, their stuttering decreases. Habit reversal is used to treat stuttering when relaxation training is paired with awareness training and psychoeducation about the nature of the disorder. Contingency management may be helpful, whereby a child is reinforced for slowing down and speaking in a more relaxed fashion.

The Lidcombe Program, an operant conditioning (direct treatment) approach, was designed by researchers in Australia. In this program, parents are trained to provide verbal contingencies in one or two 10- to 15-minute conversations per day with their child using predetermined responses for stutter-free and stuttered speech (339,340). The Lidcombe Program has demonstrated efficacy in decreasing stuttering by 9 months posttreatment (341). The Lidcombe Program was compared to another indirect treatment approach (based on the Demands and Capacities Model; RESTART-DCM; (342)) and both treatments showed a high response rate, with 76% and 71% of children classified as nonstuttering at 18 months' posttreatment, respectively (343). Stuttering has a high rate of spontaneous recovery, at nearly 63% by 3 years' postsymptom onset, which makes it difficult to determine treatment effectiveness (344).

CHAPTER 6.2.3 ■ INTERPERSONAL PSYCHOTHERAPY

LAURA MUFSON AND JAMI F. YOUNG

INTRODUCTION

Interpersonal psychotherapy (IPT) is a brief, time-limited psychotherapy that was developed in the late 1960s for the treatment of nonbipolar, nonpsychotic, depressed adult outpatients (1). The underlying assumption of IPT is that the quality of interpersonal relationships can cause, maintain, or buffer against depression. This view is similarly articulated in interpersonal theories of depression (2–4). When one is depressed, it affects one's interpersonal relationships. The quality and stability of the relationships in turn affects one's mood. IPT assumes that if one improves the relationships, one can actually change the course of the depressive episode. IPT educates individuals about the link between their mood and problems that are occurring in their relationships, and teaches them how improving their interpersonal skills and addressing these relationship problems can lead to recovery from their depression.

The emphasis on the connection between relationships and mental health has its origin in the work of Adolf Meyer (5) and Harry Stack Sullivan (6). Meyer postulated that mental illness was a result of the difficulties a person had in attempting to adapt to his environment, including his relationships. Sullivan stated that mental disorders were in part affected by inadequate communication and lack of understanding of one's behavior within relationships. In addition to these theories, IPT has its roots in Bowlby's attachment theory, specifically in its emphasis on the importance of relational bonds with other people. When there are conflicts or losses of the important bonds, the outcome is emotional distress, and specifically depression (7). Accordingly, IPT focuses on teaching individuals ways to decrease conflict and to cope with other changes in their relationships, including actual losses of relationships due to death, which can affect a person's mood.

BACKGROUND

Basic Principles

The two main goals of IPT are to: (1) decrease depressive symptoms and (2) improve social functioning within significant relationships. The strategies for achieving these goals include: (1) identifying a specific problem area; (2) identifying effective communication and problem-solving techniques to use with the problem

area; and (3) practicing in session, and eventually experimenting outside the session, with the use of these techniques in the context of significant relationships. Clinical depression is conceptualized in IPT as consisting of three components: (1) symptom formation, (2) social functioning, and (3) personality (1). IPT is conceptualized as intervening in symptom formation and social functioning and less in personality, given its short duration.

Modifications for Use with Adolescents

IPT has been selected for use with adolescents due to its developmentally relevant focus on relationships and skill-building. Interpersonal Psychotherapy for Depressed Adolescents (IPT-A) is active, structured, and includes a large psychoeducational component. As treatment progresses, the adolescent takes more control and develops a more active, action-oriented way of problem-solving (8) that is consistent with appropriate developmental changes in their approach to problem-solving (9). IPT-A emphasizes interpersonal competencies and skills training. Treatment works by addressing the difficulties and enhancing the strengths of the individual, with the goal of increasing independence and interdependence on a support system. Thus, IPT-A supports the task of individuation and increased autonomy that is so important to adolescents and therefore makes the treatment attractive to them.

Several alterations have been made to the IPT manual to increase the model's appropriateness for the treatment of adolescent depression. Although the overall goals and problem areas of IPT are employed in IPT-A, the latter also includes a discussion, within the problem area of role transitions, about transitions that are due to family structural change (e.g., divorce, separation, remarriage). This discussion of a specific type of transition is included given the frequency with which it occurs for adolescents, the empirically demonstrated connection to depressive symptoms, and the interpersonal challenges and difficulties that are associated with family transitions (10). A second adaptation is the addition of a parent component to the treatment protocol. Although IPT-A is an individual treatment, some degree of involvement on the part of the parent or guardian is needed to promote the wellbeing of the adolescent and to facilitate the success of the treatment. Parent involvement in IPT-A is flexible, though it should minimally include involvement in the initial phase of treatment so as to provide education about the disorder and its treatment. The parent may also be involved as needed in the middle phase to work on specific relationship strategies and it is best if the parent attends a final session to review his child's progress in treatment and future treatment needs. The role of the parent or guardian in treatment is presented for each phase of the treatment in the manual (11).

The objectives of treatment have been altered slightly to take into account developmental tasks including individuation, establishment of autonomy, development of romantic relationships, coping with initial experiences of death and

loss, and managing peer pressure. Second, the techniques employed in the treatment for working toward the goals of decreasing depressive symptoms and improving interpersonal functioning have been geared toward adolescents. Techniques employed with adolescents include giving them a rating scale from 1 to 10 to rate their mood, which is concrete and makes it easier for them to monitor improvement; doing more basic social skills work; conducting explicit work on perspective-taking skills to counteract adolescent black-and-white thinking about solutions to problems; and learning how to negotiate parent–child tensions. Additional strategies have been identified to address special issues that arise in the treatment of adolescents, such as school refusal, physical or sexual abuse, suicidality, aggression, and involvement of a child protective service agency.

Overview of Efficacy

IPT-A meets four conditions that permit its inclusion as an efficacious treatment: (1) the treatment is manual based (1,11); (2) the sample characteristics are detailed; (3) the treatment has been tested in randomized clinical trials (12–16); and (4) at least two different investigator teams demonstrated the intervention's effects (17–19). In addition, IPT-A has been evaluated and included as an efficacious treatment in SAMHSA's National Registry of Evidence-Based Programs and Practices. The efficacy and effectiveness of IPT-A for reducing adolescents' depressive symptoms have been examined in five randomized controlled clinical trials (12–16). Depressed adolescents treated with IPT-A demonstrated fewer depressive symptoms, better social functioning, and better global functioning at the completion of treatment than adolescents in control conditions, although in one study (15), IPT did not show as much improvement as CBT.

The efficacy clinical trial conducted by Mufson et al. (12) included adolescents who met DSM-III-R criteria for major depression. The study showed that IPT-A (N = 24) was superior to clinical management (N = 24) (monitoring of symptoms) with respect to decreasing depressive symptoms, rates of recovery from depression, and rates of retention in the treatment for depressed adolescents. In addition, adolescents who received IPT-A demonstrated significant improvement in certain areas of social functioning and interpersonal problem-solving skills compared to adolescents who received clinical management.

Rosselló and Bernal (13), who used a different modification of the adult IPT manual (20), provided independent replication in their study that showed that both IPT (N = 23) and CBT (N = 25) were superior to waitlist control (N = 23) for the treatment of depressed adolescents (N = 71) who met DSM-III criteria for major depressive disorder, dysthymic disorder, or both. They also found that IPT was significantly better than the waitlist condition at increasing self-esteem and improving social adaptation. They found that 82% of the adolescents receiving IPT

compared to 52% of the adolescents receiving CBT met recovery criteria by the end of treatment. In a second study, Rosselló et al. (15) conducted a randomized controlled trial comparing the efficacy of group versus individual IPT, and group and individual CBT for adolescents with depression (either diagnosis or significant severity of symptoms) and reported no significant differences between individual and group formats. On most measures, there were no significant differences in outcomes between IPT and CBT treatments. However, CBT produced significantly greater decreases in depressive symptoms than IPT. It is important to note that there was low fidelity adherence to the IPT treatment in this study, which may explain the weaker results for IPT.

Recently, another research group compared the efficacy of group to individual IPT-A for a primary diagnosis of major depressive disorder (16). Thirty-nine adolescents, aged 13 to 19 years, were randomly assigned in blocks to either group or individual delivery of IPT. Treatment was adapted for group delivery taking into account the recommendations of Mufson et al. (21) and Wilfley et al. (22). There were significant improvements in depression, anxiety, and global functioning from pre- to posttreatment for the sample and no significant differences in outcome between group and individual formats of delivery (16). In secondary data analyses, adolescents showed significant improvements in interpersonal functioning and changes in attachment style following treatment (23). This study provides additional empirical support for IPT-A in both an individual and group format for the treatment of depression. Although tests of mediation were not possible in this sample, their findings suggest that improvements in interpersonal relationships are a possible mechanism of the intervention.

Additional empirical investigations of IPT-A aim to reach a broader range of depressed adolescents by either providing treatment in community-based practice settings or serving more severe populations. For instance, an effectiveness study compared IPT-A to treatment as usual (TAU) in the school-based health clinics in New York City for depressed adolescents with a broader diagnostic picture including major depression, dysthymia, depression disorder NOS, and adjustment disorder with depressed mood (14). In addition, adolescents were included with comorbid diagnoses including anxiety disorders, ADHD, and oppositional defiant disorder. School-based clinicians delivered both treatments. TAU consisted mostly of individual supportive counseling, typical of care delivered in the schools prior to initiation of the study. Adolescents treated with IPT-A compared to TAU showed greater symptom reduction, significantly better social functioning, and greater decrease in clinical severity of depression and improvement in overall functioning. In addition, the study demonstrated the ability to train community clinicians to deliver IPT-A effectively using an abbreviated therapy training program, thereby demonstrating the transportability and effectiveness of IPT-A from the university laboratory to the community setting (24).

Another study was conducted in a high school comparing intensive IPT-A (IPT-A-IN) to TAU (supportive counseling) for depressed adolescents with suicidal risk, although adolescents at imminent risk for suicide were excluded and referred for a higher level of care (25). The treatment was modified; IPT-A-IN consisted of two 50-minute face-to-face sessions weekly and a 30-minute phone follow-up weekly for a total of three clinical contacts per week. Due to the increased frequency of sessions and desire to intervene quickly, the duration of treatment was also shortened to 6 consecutive weeks instead of 12 weeks. The students were identified in school through depression screenings using self-report measures and then evaluated by a psychiatrist for depression and suicide severity by a psychiatrist using a structured diagnostic interview. The sessions were delivered by well-trained school counselors and treatment targeted both the depression and suicidal ideation linking these symptoms to problems in the students' relationships, consistent with IPT-A. Intensive school-based IPT-A-IN was shown to be effective in reducing the severity of depression, suicidal ideation, anxiety, and hopelessness in depressed adolescents with suicidal risk (25).

The efficacy and effectiveness studies demonstrate IPT-A's acceptability, efficacy and effectiveness for a broad cultural population of adolescents from impoverished urban Latinos to adolescents in Japan, Australia, and Puerto Rico (12–15,16,25). IPT-A appears effective both with lower income as well as middle class populations. Age and severity of illness were identified as moderators of IPT-A outcome in the effectiveness study. Older adolescents (15 to 18 years.) and those who were more severely ill showed a greater benefit of being treated with IPT-A than TAU (14). Depressed adolescents with comorbid anxiety who received IPT-A had a better treatment outcome than those who were treated with TAU (26). Finally, IPT-A has been shown to be particularly effective for adolescents with high levels of parent–adolescent conflict (27). To date, there are no identified mediators of IPT-A outcome, in part due to the smaller sample sizes of the IPT-A studies, however the recent study by Spence et al. (23), suggests that change in interpersonal functioning is one possible mediator. Further research is needed to better understand the moderators and mediators of IPT-A. Based on the empirical support for treatment efficacy, IPT-A meets the American Psychological Association Division 12 criteria for a "well-established" psychotherapy for depression in youth (19).

Who Is Suitable to Treat with IPT-A?

An integral part of the assessment process is determining an adolescent's suitability for IPT-A based upon diagnosis, severity of illness and impairment, as well as an assessment of the family environment and willingness to engage in treatment. Based on our clinical experience, the following characteristics of an adolescent make IPT-A a good treatment choice: (1) the adolescent's willingness to work in a one-to-one

therapeutic relationship in a time-limited therapy; (2) recognition by the adolescent that there seem to be difficulties of an interpersonal nature that may be causing problems at this time; and (3) a family willing to support the therapy or at least allow the adolescent to participate in treatment.

An adolescent is felt to be suitable for treatment first and foremost if he is willing to acknowledge the depression and is willing to discuss the impact the depression is having on his relationships. An adolescent who is willing to discuss feelings and problems, and explore connections among feelings, events and relationships, is a particularly good candidate for IPT-A. IPT-A is probably most effective with adolescents who have had an acute onset of depressive symptoms and historically have not had chronic and severe interpersonal problems with friends or family. The acute onset increases the likelihood of being able to identify an interpersonal precipitant to the depression and/or exacerbation of a longer-standing interpersonal problem. IPT-A may also be helpful to adolescents with long-standing interpersonal problems, but the goals for improvement may need to be more circumscribed.

IPT-A is designed for use with adolescents, ages 12 to 18 years, who have an acute onset of major depression or other milder forms of depression such as dysthymia, an adjustment disorder with depressed mood or depression not otherwise specified. Adolescents are suitable for the treatment if they are of normal intelligence, and are not actively suicidal. Many of the treated adolescents report suicidal ideation consisting of passive thoughts about wanting to be dead but they typically do not report intent to die or a specific plan to harm themselves. The therapist must feel that once-a-week therapy is sufficient and safe for the adolescent's current level of depression. Tang et al.'s study (25) suggests that twice-a-week therapy may be an effective model for those with elevated suicide risk. Depressed adolescents with psychotic symptoms or primary diagnoses of bipolar disorder, substance abuse, or conduct have not been treated with IPT-A. Initial studies have examined the efficacy of treating bipolar adolescents with Interpersonal and Social Rhythms Therapy for adolescents (IPSRT-A) (28). However, depressed adolescents with comorbid anxiety disorders, attention-deficit disorder, and oppositional defiant disorder have been treated successfully with IPT-A. If the adolescent has comorbid disorders, a decision should be made confirming that the depression is the appropriate disorder upon which to focus treatment initially.

Prior to the initiation of IPT-A, a thorough diagnostic evaluation of the adolescent should be undertaken to gather information on current symptoms as well as previous psychiatric, family, developmental, medical, social, and academic history. The goals of the diagnostic assessment are to: (1) make a current clinical diagnosis using DSM-5 diagnostic criteria; (2) ascertain the adolescent's level of psychosocial functioning and pinpoint areas of interpersonal problems; and (3) assess which treatment would be most appropriate for the adolescent. This evaluation should be conducted by an intake clinician and/or the IPT-A therapist prior to initiating treatment. Such

information should be gathered during the evaluation from the adolescent, parents and other family members, teachers and other school personnel, and other caretakers such as pediatricians and clergy to facilitate an informed decision about the treatment of choice for the teen (11).

INITIAL PHASE OF THERAPY

IPT-A is divided into three phases: initial, middle, and termination. There are three main components of IPT-A that are evident in the three phases of treatment (Table 6.2.3.1). The initial phase focuses primarily on the first component of psychoeducation with some attention to affect identification. The middle and termination phases focus more directly on affect identification and interpersonal skill building techniques and prevention of relapse.

Psychoeducation about Depression and IPT-A

There are several tasks to be accomplished during the first session of IPT-A. These include: (1) explaining the nature of depression in adolescents; (2) assigning the limited sick role in treatment; and (3) introducing the basic principles of IPT-A. It is preferable to involve the parents in the first session by dividing the initial IPT-A session into a combination of meetings with the adolescent and parent together, adolescent alone, and parent alone as was done in the pretreatment evaluation. At the conclusion of the initial session, the adolescent and parent(s) should know that the depression symptoms are (a) time limited, (b) reflective of a disorder which can be treated successfully, and (c) that the adolescent will likely be able to function better with treatment.

Explaining the Nature of Depression in Adolescents

An important task of the first session is to impart information about the course of depression and its treatment to both adolescent and family. This should include a discussion about the symptoms of depression, their impact on functioning, and the prevalence rates of depression in adolescents. It is important for the adolescent and family to know that the prognosis for recovery is good. The adolescent and the parent(s) also need to be informed that there are other treatment options available, including other forms of psychotherapy and/or medication if for some reason IPT-A is not sufficiently effective for this adolescent.

TABLE 6.2.3.1

INTERPERSONAL PSYCHOTHERAPY: PRIMARY COMPONENTS OF TREATMENT

Education	Affect Identification	Interpersonal Skills Building

- Psychoeducation
- Limited sick role
- Interpersonal inventory
- Treatment contract

- Labeling emotions
- Clarification of emotions
- Facilitating expression of emotions
- Monitoring emotions

- Modeling
- Use of therapeutic relationship as sample of interpersonal interaction
- Communication analysis
- Perspective-taking
- Interpersonal problem solving
- Role-playing

Giving the Adolescent a Limited "Sick Role"

The purpose of the limited sick role is to allow the adolescent some relief from the pressure of performing his usual social role at the same level as prior to being depressed, and to receive some extra support for his efforts without punishment for the quality of the work while he recovers. The adolescent and his family are encouraged to think of him as in treatment and as having an illness that affects his motivation and the quality of his performance. Nonetheless, the adolescent is encouraged to maintain the usual social roles in the family, at school, and with friends. Specifically, he needs to get up every morning and get to school, participate in his usual school activities, complete homework, and perform his chores around his house to the best of his abilities. The parent is advised to be supportive, less punitive, and to encourage the adolescent to engage in as many normal activities as possible, while recognizing that the adolescent may have difficulty performing up to par. The assignment of the sick role and psychoeducation can help family members to respond more positively toward the adolescent and shift the blame for difficulties in fulfilling his social roles from the adolescent to the illness (11).

Education about IPT-A

At this point in the session, it is a good idea to introduce the basic structure of IPT-A to the adolescent. The therapist restates that the focus of treatment will be on reducing the depression symptoms he is experiencing and improving relationship difficulties that seem most connected to his depression. The therapist and adolescent together will identify and practice strategies and skills to improve the targeted relationships and in turn improve his mood. Most of the sessions will occur with the therapist and adolescent alone, but they may talk about inviting parents or significant others into a session or two in the middle phase if it looks like it might be helpful.

Interpersonal Inventory

In the remainder of the initial phase, the therapist conducts the interpersonal inventory, which is a detailed review of the adolescent's significant relationships, both current and past. To conduct the interpersonal inventory, it is helpful for the therapist to use the Closeness Circle (Figure 6.2.3.1). This is a series of concentric

circles with the adolescent's name in the center. The goal is to place the adolescent's significant relationships within the appropriate circles of closeness/importance in the teenager's life. The result is a picture of the significant people orbiting the adolescent's life and the emotional valence associated with their position in the adolescent's life.

Once the circle has been completed, the therapist asks detailed questions about each relationship. Examples of questions from the inventory are: "What is your relationship with X like?" "What do you like about X? What don't you like? What types of things do you do with X? Do you ever argue?" The therapist should use these questions to facilitate the adolescent's telling the story of his current life as played out in his significant relationships. It is important when conducting the interpersonal inventory to obtain information about relationships that illustrate interpersonal strengths as well as those that illustrate deficits or areas of weakness.
FIGURE 6.2.3.1. Example of a closeness circle.

The interpersonal inventory facilitates the adolescent and the therapist's

understanding of the interpersonal context of the depression. The therapist gathers information about events that may have precipitated the depressive episode, the reasons for seeking treatment now, and what has been happening in these significant relationships that may be associated with the onset of symptoms. Although the emphasis is on current relationships, obtaining a complete picture of the adolescent's social relationships including some information about past relationships and interpersonal functioning is helpful in understanding his overall patterns of interaction and communication in his relationships. The therapist can think of it as the diagnostic assessment of interpersonal symptoms to parallel the completed assessment of depression symptoms. This inventory provides the necessary interpersonal data to select one of the four problem areas for focus in the middle phase.

Formulation of Problem Area and Making a Treatment Contract

By the end of the fourth session, the therapist will have completed a comprehensive interpersonal assessment and will conclude the session with an interpersonal formulation linking the adolescent's interpersonal situation with his depressed mood and placing the formulation within the framework of one of the four problem areas. The problem area formulation should occur as a natural outgrowth of the recent discussions. It is helpful for the therapist to weave the narratives of each relationship into one larger interpersonal narrative for the adolescent, pointing out any noticeable patterns across relationships. The therapist should seek the adolescent's opinion of the formulation, giving the adolescent the opportunity to acknowledge the issues, show understanding, and have the opportunity to disagree.

As in the adult version of IPT, there are four identified problem areas in IPT-A upon which the therapy can be focused: (1) grief due to death; (2) interpersonal disputes with friends, teachers, parents, and siblings; (3) role transitions such as changing schools (elementary to junior high or junior high to high school), entering puberty, becoming sexually active, birth of another sibling, becoming a parent, parental divorce, illness of a parent; and/or (4) interpersonal deficits such as difficulty initiating and maintaining relationships and communicating about feelings (11). Grief is defined in IPT-A as loss through death. The grieving process can be abnormal by being delayed, distorted, or by becoming a chronic reaction. Interpersonal disputes are conceptualized as a situation in which the adolescent and other parties have diverging expectations of a situation and this conflict is severe enough to lead to significant distress. Role transitions are situations in which the adolescent is having difficulty adapting to a change in life circumstances. These may be developmental crises or adaptations following life events or relationship dissolutions. Finally, interpersonal deficits is identified as the problem area when an

adolescent has impoverished interpersonal relationships in both number and quality of the relationships. When there seem to be two problem areas, the therapist should identify a primary and possibly a secondary problem area to work on in treatment.

Setting the treatment contract involves outlining the adolescent's and parents' roles in the treatment, identifying treatment goals, clarifying expectations for treatment, and outlining the nuts and bolts of treatment. Both the improvement in interpersonal functioning and reduction of symptoms are equally important achievements and most frequently will co-occur. Therapist and adolescent should set goals that are likely to be attainable within the brief treatment so that the adolescent can feel the goals were achieved and can have a sense of progress throughout the treatment. The culmination of this discussion is a specific verbal treatment contract.

MIDDLE PHASE OF THERAPY

Following agreement on the treatment contract and the identified problem area, the middle phase of treatment begins. Typically this occurs by session 5 and continues through session 9. Session 9 is a transitional session in which the work of the middle phase continues while the therapist begins to discuss concluding the treatment in several weeks. The middle sessions focus on the problem area identified in the initial sessions as a means toward achieving recovery from depression. The objectives of the middle phase of treatment for all adolescents include: (1) further clarification of the problem area; (2) identification of effective strategies to attack the problem; and (3) implementation of interventions to bring about resolution of the problem. The therapist's general tasks associated with the middle phase of treatment are as follows: (1) monitoring depression symptoms and the need to consider adjunctive therapy such as medication if there is no improvement or a worsening of symptoms; (2) facilitating the adolescent's self-disclosure of his affective state; and (3) keeping in contact with parents to support and participate in treatment as necessary (11).

During the middle phase of treatment, the therapist and adolescent continually assess the accuracy of the initial formulation of the problem to maximize the amount of change that can be accomplished in the treatment. The therapist must keep the adolescent's discussions relevant to the identified problem areas. The therapist helps generate strategies and suggests the application of techniques that will lead to clarification and resolution of the adolescent's problem. This includes illuminating the process of identifying problems, clarifying the issues, generating strategies, applying strategies for problem resolution, and acquiring skills that result in increased interpersonal self-confidence and improved functioning.

Work on the Identified Problem Area

The therapist and adolescent work to resolve the identified problem area during the

middle phase of treatment. In the case of grief, the IPT-A therapist helps by reconstructing the adolescent's relationship with the deceased, addressing unresolved issues in the relationship, linking the depression to the feelings for the deceased, providing empathic listening to help facilitate the mourning process, and assisting the adolescent in establishing new relationships. The IPT-A therapist can use these strategies to similarly help adolescents who are suffering while in the midst of the normal grieving process. In cases where interpersonal disputes are the identified problem area, IPT-A aims to define how intractable the dispute is, the specific stage of the dispute, and identify sources of misunderstanding via faulty communication, poor perspective-taking, and invalid or unreasonable expectations. The therapist aims to intervene by using communication training, problem-solving, or other techniques that facilitate change in the situation.

In the middle phase of treatment, IPT-A for role transitions aims to help the adolescent to reappraise the old and new roles, to identify sources of difficulty in the new role, identify skills and strategies that would make it easier to adapt to the new role, and to develop skills and implement solutions for these difficulties in their significant relationships. Finally, in the case of interpersonal deficits, the adolescent and therapist will need to focus upon old relationships as well as the relationship with the therapist during the middle phase. In the former, common themes should be identified and linked to current circumstances. In using the therapeutic relationship, the therapist aims to identify problematic processes, such as deficits in initiating or maintaining relationships, and to modify these processes by practicing approaches to developing new relationships. By practicing the interpersonal skills with the therapist, the therapeutic relationship can serve as a template for other relationships that the adolescent will be striving to develop.

Therapeutic Techniques

During the middle phase of the treatment, the therapist teaches the adolescent specific strategies that can help him deal with his interpersonal difficulties within one or two of the problem areas. The therapeutic relationship in IPT-A provides a forum in which skills can be practiced and feedback can be given in a nonthreatening environment (11). IPT-A techniques include exploratory techniques, encouragement of affect, communication analysis, behavior change techniques (including decision analysis and role plays), use of the therapeutic relationship and adjunctive techniques such as interpersonal experiments. Exploratory techniques can be either directive or nondirective. Directive exploratory techniques include targeted questioning and interviewing. The nondirective techniques include supportive acknowledgment, and extension of the topic being discussed by the adolescent (11). Encouragement of affect involves facilitating discussion of painful feelings about events or issues and helping the adolescent use his affective experiences to better understand the link

between mood and relationships and eventually to make interpersonal change.

Communication analysis is a thorough investigation of a specific dialogue or argument that occurred between an adolescent and another person. Communication analysis identifies ways in which the adolescent's communication is ineffective and fails to achieve the goal of the communication. In conducting the communication analysis, the therapist can illustrate how changing one phrase can change the entire feeling about the interaction and the other person. Decision analysis is employed by the therapist to help the adolescent consider a range of alternative actions that he can take and the possible consequences associated with each of those actions. In role-playing, the therapist and adolescent act out the skills that the adolescent is learning in the treatment in a nonthreatening way. The therapist can model many useful interpersonal skills such as affective expression, effective communication, and decision-making strategies. Adjunctive techniques include work assignments to be done at home between the sessions. The assignments usually involve practicing specific skills that were the focus of the sessions. They are referred to as "interpersonal experiments" or "work at home."

TERMINATION PHASE

A termination date is set with the adolescent and family at the beginning of treatment and the adolescent is reminded of the number of weeks remaining until the end of treatment. Twelve weeks is the time frame chosen for the clinical trials assessing the efficacy of IPT-A. It is a reasonable duration for adolescents who are reluctant to stay in treatment for any significant length of time. The time period can be modified in either direction. The important issue is to retain the treatment's time-limited nature by setting the initial treatment contract for the number of weeks that seem most appropriate for that adolescent.

Tasks of Termination

The termination phase includes clarification of the adolescent's warning symptoms of future depressive episodes, identification of successful strategies that were used in the therapy, generalization of skills to future situations, emphasis on mastery of new interpersonal skills, and discussion of the need for further treatment (11). The therapist needs to balance the tasks of the termination phase with concluding work on the identified problem area. It is crucial to devote a major portion of the termination phase to reviewing interpersonal strategies used during the middle phase and to applying these strategies to ongoing and future situations. This may help reduce relapse and recurrence, which are common in adolescent depression, improve social self-confidence, and enable the adolescent to negotiate successful endings of other relationships at future points in his life.

Throughout the treatment and termination, the therapist should identify the changes that she observes in the adolescent: improved communication and ability to see another person's perspective, attempts made to negotiate a dispute, increased awareness about his own feelings associated with a relationship, successful mourning of the loss and/or the establishment of new relationships. The therapist and adolescent together highlight how specific strategies have enabled him to make improvements within his identified problem area, in specific relationships, and most importantly in his mood.

Terminating treatment with an adolescent also means terminating treatment with the family. Ideally, the therapist will conduct a final termination session with the adolescent alone and then have another joint termination session for the adolescent and family. The therapist also may see the parents alone if necessary or if the adolescent prefers it that way. The goals of the final session for the family are similar to those of the adolescent's final session: a review of the adolescent's presenting symptoms, initial goals for the therapy, achievement of these goals, and a discussion of the changes in the family interactions and functioning as a result of the therapy. The termination phase enables both the adolescent and parent to participate in the review of accomplishments and the identification of areas that would benefit from further treatment. It is important to discuss with the family the possible recurrence of mild symptoms shortly after termination, the need for further treatment if it is indicated, and management of future recurrent episodes of depression.

There are adolescents for whom there has been some improvement, but who are still moderately symptomatic at the conclusion of treatment. Further treatment may be necessary under certain circumstances when the symptoms have not fully remitted or when there are other more chronic problems contributing to the adolescent's impairment. This information is utilized by the family, adolescent, and therapist to make decisions about the need for further treatment and the type of additional treatment that may be needed.

SPECIAL ISSUES

Working with Parents

Due to high divorce rates as well as increases in single-parent families, adolescents often live in nonnuclear families, including homes of other relatives and foster or group homes. As with the parents, these people are important in the adolescent's daily life and must be educated about the nature of depression, ways to support the adolescent's recovery and, if necessary, participate in the treatment to facilitate changes in the home environment that will play a role in the adolescent's recovery.

Awareness and understanding of the mental health status of an adolescent's parent or guardian is critical to understanding the adolescent's depression and developing

the most effective treatment plan. In cases where the parent is depressed, it is often necessary for the adolescent's therapist to help the adolescent by first helping the parent find an appropriate referral for her own treatment. It is important to explain that in the IPT-A framework, depression affects the parent's as well as the teen's interpersonal functioning. Any alleviation of parental depression is likely to reduce the stress the adolescent is facing.

Depressed parents often model a depressive interpersonal style that can range from ineffective communication and conflict negotiation skills to social withdrawal and helplessness. Therefore, when these adolescents try to practice new interpersonal skills at home, they face an uphill battle. In such cases, the therapist and adolescent will need to do more in-session practice of interpersonal strategies as well as have the adolescent identify others in his life with whom he can practice these skills. Enlisting the parent as a "coach" and "collaborator" in the treatment can foster the parent's willingness to support the adolescent's experiments with new skills, both during and outside of the session. Having a good grasp of the role of parental depression in the family allows the adolescent and therapist to develop realistic treatment goals and focus on the relationships that can have the greatest impact on increasing his feelings of support and decreasing his depressed mood (11).

Not all parents, unfortunately, are open to intervention for themselves or their child. In these situations, the therapist should, with the adolescent's approval, attempt to intervene with the parent during an in-person meeting, or over the phone if the parent is unable to attend a session. The therapist, using an empathic and nonjudgmental psychoeducational approach, can sometimes alter the parent's perspective and enjoin them to support the treatment. If the parent continues to be resistant to collaborating in the treatment, the therapist will need to work with the adolescent on a modified treatment plan.

Use of Medication with IPT-A

The use of IPT-A in combination with medication has not been studied in a large clinical trial; however, it is frequently used this way in our general outpatient psychiatry clinics with benefits to the adolescent and we have obtained some initial pilot data supporting combined treatment (29). Most of the clinical trials have included a homogeneous sample of adolescents who typically have a depression disorder with a possible anxiety disorder, and have excluded adolescents with other disorders such as conduct disorder or substance abuse (24). However, in treatment in outpatient clinics, adolescents may present with depression and other comorbid disorders that may require a combination of medication and IPT-A. Antidepressant medication is not contraindicated during IPT-A, and in fact, may be a useful adjunctive treatment for severely depressed adolescents whose symptoms do not remit during the initial phase of treatment. The main goal of any acute phase of

treatment, medication or psychotherapy, is to achieve a timely treatment response measured by remission of the depressive symptoms. Therefore, if the adolescent is not responding as well as one would like to the therapy, it is advisable to consider adding an adjunctive treatment.

Our guidelines are to consider antidepressants if there is little or no remission of symptoms after 4 weeks of IPT-A. Experience treating adolescents suffering from a more chronic depression (either dysthymia or chronic major depression) suggests that medication might be beneficial from the outset of treatment to help alleviate the hopelessness and listlessness that often characterize these adolescents and prevent them from more actively engaging in psychotherapy (11). The clinician should discuss with the adolescent and his parents the reasons for considering medication: that the adolescent is still showing significant signs of depression or significant anhedonia and lethargy, and that in such instances medication can often be beneficial. These guidelines evolved from our clinical experience using IPT-A to treat depressed adolescents. Recently, a pilot study examining the feasibility and acceptability of delivering a stepped care model of IPT-A in pediatric primary care which included a combined IPT-A and medication arm was completed. This study suggested that IPT-A and medication, in this case Prozac, can be an acceptable and potentially effective treatment for adolescent depression. It was, however, a small sample that received the combined treatment since a significant number of adolescents showed improvement after 8 weeks of IPT-A alone (29). Thus, more research is needed to assess the efficacy of using both medication and IPT-A to treat adolescent depression and its comorbid disorders.

Crisis Management

Crises are not infrequent during the treatment of a depressed adolescent. A crisis is a major change in the adolescent's living situation, interpersonal relationships, family relationships, or emotional well-being that jeopardizes the adolescent's psychological health and overwhelms the adolescent's capacity to cope with the situation. Examples of crises include: running away, pregnancy, illness in family or friend, involvement with the law, exposure or involvement in violence. The first task facing the IPT-A therapist is to determine the nature and etiology of the crisis by speaking both to the adolescent and other parties involved. In the case of suicidal or homicidal ideation, if an appointment cannot be set up soon enough, the adolescent should be sent to the nearest emergency room to evaluate the need for hospitalization or an increase in the frequency and intensity of the treatment. The therapist's most important decision is whether or not the adolescent can remain in IPT-A or whether the adolescent must receive other types of services either at the same or another facility.

If the adolescent is evaluated as being able to remain in outpatient adolescent

treatment, the IPT-A treatment contract should be reexamined and revised as necessary. Items in the contract that may change include the frequency of the sessions, involvement of the family, frequency of phone calls between the therapist and adolescent, and the identified problem area that is the focus of the treatment. At times the crisis may suggest that a significant problem area was overlooked or there may be an interaction between two problem areas, thus requiring a shift in the focus of the sessions. With the new contract, the therapist can move forward to address the new information about the adolescent's interpersonal relationships and the context of the depression.

TRAINING IN IPT-A

In the IPT-A efficacy study, therapists received 2 days of didactics and then treated three cases for training purposes, videotaping every session and receiving 1 hour of supervision for each session. A random selection of these tapes was rated by experts for therapist competency prior to certifying the therapists to participate in the clinical trial. Such an intensive training program is not feasible in effectiveness research due to constraints on the clinicians' time, nor is it realistic for training clinicians to implement the treatment in their practices. Clinicians in community-based settings routinely have pressing clinical demands competing for their time so that the training program in the effectiveness study was abbreviated to one full day of didactics and the practice cases characteristic of the efficacy trials were eliminated. Even with this briefer training, clinicians were able to learn IPT-A and deliver it with enough fidelity to obtain good outcomes (24). Such support for briefer training and supervision models is needed in order to be able to disseminate and implement treatment in the community in a cost-effective manner.

Nonetheless, when it comes to training and certifying clinicians as IPT-A therapists, the intensity of the efficacy model of therapist training is still believed to produce the best adherence and competence in IPT-A. In addition, to be considered for training to be an IPT-A supervisor and trainer of other clinicians, at least another two treatment cases with supervision (total = 5) are typically required, along with consultation on the supervision of several cases to ensure that the therapist feels confident and can competently train others in the use of the IPT-A model. The International Society for Interpersonal Psychotherapy (ISIPT) is currently working to settle upon guidelines for the training and certification of IPT therapists.

CONCLUSIONS

IPT for depressed adolescents (IPT-A) is an evidence-based psychotherapy that is based on the premise that depression occurs in an interpersonal context. The goals of

treatment are to improve the adolescent's interpersonal relationships and his depression symptoms. IPT-A is defined in a treatment manual that is adapted to address the developmental needs of adolescents and their families in a time-limited approach (11). IPT-A is unique in that it has been demonstrated to be effective both in the laboratory and community setting and when delivered by expert and community clinicians (12–16,25). Furthermore, IPT-A has been demonstrated to be efficacious with an underserved Latino population that typically has less access to treatment services (12,14). Research studies and clinical experiences point to the utility of IPT-A as a treatment for adolescent depression. Clinical experience and a pilot study further suggests the benefits of combining IPT-A with medication for adolescents with more severe depression. However, a larger controlled clinical trial is needed to further examine this question.

CHAPTER 6.2.4 ■ PARENT TRAINING

KAREN BEARSS, T. LINDSEY BURRELL, VALENTINA POSTORINO, AND LAWRENCE SCAHILL

INTRODUCTION

Child disruptive behaviors such as whining, crying, tantrums, aggression, and noncompliance are common concerns among parents. When these behaviors reach levels of clinical significance, children may qualify for *Diagnostic and Statistical Manual*—Fifth Edition (DSM-5) diagnoses of oppositional defiant disorder (ODD) and conduct disorder (CD) (childhood onset, adolescent onset, unspecified onset). ODD and CD fall under the category of disruptive behavior disorders (DBDs) and are broadly characterized by problems in behavioral and emotional self-control. When these challenging behaviors persist and impair functioning in the home, school, and community, intervention is warranted. With over half of all referrals to community child mental health clinics focused on oppositional or aggressive behaviors, DBDs are one of the most frequent treatment referrals (1,2). The prognosis for children with significant disruptive behavior problems is poor, with pervasive and unremitting aggression and conduct problems in childhood reliably predicting delinquent, aggressive, and risky behaviors in adolescence (3,4). Adults who exhibited conduct problems in childhood are more likely to have a range of psychiatric disorders and to engage in "life-course–persistent" antisocial behavior, including crime, drug abuse, domestic violence, and child abuse (5–7).

In child mental health services, parent training (PT), also referred to as "parent management training," describes a group of treatments that target disruptive and noncompliant behavior in children and adolescents. Parents are trained to implement specific procedures designed to improve parent–child interactions (8), decrease problematic behaviors, and increase prosocial behaviors (9) by (a) attending to the child's prosocial behaviors, (b) ignoring the child's inappropriate behaviors, (c) decreasing the use of punitive and coercive discipline strategies, and (d) increasing the use of effective, appropriate, *noncoercive* child management strategies to improve parent–child interactions.

PT sessions are structured and treatment is short term, averaging 10 to 12 weekly sessions. Programs vary to some degree in content presented (e.g., knowledge of typical child development, parental self-efficacy, communication skills, discipline or behavior management strategies) (10) and can be conducted in a variety of settings (home, community clinic) and formats (group, individual) (11–13). Delivery techniques used to engage parents and teach relevant content include didactics, modeling, role play, and live action coaching of techniques, and assignment of homework (10).

EVIDENCE-BASED PARENT TRAINING PROGRAMS

With over 40 years of controlled studies proving benefits in reducing disruptive behavior in youth from preschool to adolescence, PT is among the most well-established evidence-based treatments in child mental health (12,14). This body of evidence has influenced international dissemination of PT and prompted several clinical practice guidelines in the United States, United Kingdom, and elsewhere in an effort to raise standards of mental health care for youth (15,16).

Although the primary targets of PT include disruptive and noncompliant behavior, programs have also been shown to promote other positive outcomes such as improved parental warmth, decreased parental hostility, increased parental knowledge, and reduced parent stress (10,17). There also is evidence suggesting that parental self-efficacy and mental health problems, such as maternal depression, improve with PT (18–23). Finally, research on PT extends beyond efficacy trials to investigations of positive effects when delivered in "real-world" community clinic settings (14).

The largest body of evidence for PT supports application in children ages 3 to 12 years with disruptive behavior and average intelligence. There is growing evidence that PT can also be effective for targeted clinical populations (child maltreatment, postdivorce adjustment) (24–26) as well as other diagnostic conditions (separation anxiety) (27). Disruptive behavior is common in children with autism spectrum disorder (28,29). Emerging literature indicates that that PT is effective in this population (30).

THEORETICAL FOUNDATIONS OF PARENT TRAINING

The conceptual framework and theoretical underpinnings of most evidence-based PT programs for behavior problems are based on a combination of Diana Baumrind's work on parenting styles (31,32), Hanf's two-stage operant behavior model (33), Patterson's coercion model (21), and operant and social learning theory.

Baumrind (31,32) described three models of parental control: permissive, authoritarian, and authoritative. Permissive parenting involves acceptance of the child's behaviors and employs collaborative decision-making between the parent and child, while placing few demands and expectations on the child. Authoritarian parenting sets defined rules on child behavior, holds standards against which the child's behaviors are evaluated, and implements strategies to teach obedience. Finally, authoritative parenting directs the child's activities while allowing the child to provide input into decision-making (31,32). The authoritative parenting style also allows for nurturance between parent and child, while also setting appropriate limits on child behavior. PT is consistent with the combined and balanced parenting approach of authoritative parenting. It includes strategies explicitly designed to

promote warmth between parent and child, but also defines boundaries and expectancies for child behavior.

Hanf's two-stage operant model provides the foundation to teach effective authoritative parenting, as described by Baumrind. The first stage involves the use of differential reinforcement (providing positive social attention and praise to appropriate prosocial behaviors while removing attention for inappropriate or disruptive behaviors) in order to build the relationship between the parent and child. The second stage promotes the use of direct commands followed by immediate consequences (e.g., time-out for noncompliance; praise for compliance). This model provides the foundation to Parent–Child Interaction Therapy (34) as well as other PT models described in this chapter (9,35,36).

Patterson's coercion model demonstrates the cycle that persists in the relationship between a parent and child that exacerbates the child's disruptive and defiant behavior (21). Patterson's model emphasizes the influence of the parent's behavior on the child and the impact of the child's behavior on the parent. In some families, parent–child relationships are characterized by aversive patterns of negative interactions (e.g., parent yells at the child and, in turn, the child whines or yells back at parents) and the tendency to handle problems in a coercive, negative manner (e.g., resorting to spanking as a discipline strategy). In addition to having negative interaction patterns, there are generally lower rates of positive parent–child interactions and children tend to model their parents' physical and verbally aggressive behaviors (e.g., yelling). A parent who is unsuccessful in using noncoercive parenting strategies, such as redirection when managing the child's behavior, frequently resorts to aversive control strategies, which sets up a pernicious pattern of parent–child interaction (37).

Understanding the development and maintenance of behavior problems has also been aided by social learning theory (38) and operant conditioning (39). Social learning theory describes the process in which people learn through direct experience, observation, and modeling. This framework provides insight into the way children may learn to engage in specific behaviors that they have observed. For example, a child may hit another child on the playground in order to gain access to a ball based on the observation that aggression was successful when used by another child. This process of observing and imitating a model also occurs in the family. Rather than implying that the child or the parent is independently responsible for the child's maladaptive behavior, social learning theory directs attention to the interactions between family members as a source of child behavior difficulties.

A child may initially engage in disruptive behavior through observation and imitation of others. Whether or not the child *continues* to engage in that behavior can be explained through principles of operant conditioning. The organizing principle of operant conditioning is that a behavior can be modified (increased or decreased) through the manipulation of its antecedents and/or consequences. An antecedent is the

stimulus that cues an organism to perform a behavior. When an organism perceives an antecedent stimulus, it behaves in a way that is designed to maximize the reinforcing consequences and minimize punishing consequences. A consequence is the event that immediately follows the behavior. The consequences of reinforcement and punishment are the core tools through which operant behavior is modified. Positive reinforcement (e.g., providing praise for cleaning up toys) and negative reinforcement (e.g., taking an aspirin to "remove" a headache) increase the probability of a behavior. By contrast, positive punishment (e.g., scolding for not following directions) and negative punishment (e.g., removing a favorite toy for hitting) reduce the probability of a behavior that it follows.

Operant conditioning is a core component of applied behavior analysis (ABA), which is classically defined as the systematic application of interventions based upon the principles of learning theory. The aim of ABA is to promote socially appropriate behavior, reduce maladaptive behavior, and demonstrate that the interventions employed are responsible for the improvement in behavior (40). ABA formulates that, by understanding a behavior's antecedents and consequences, one can determine its purpose, or *function*. Common functions of disruptive behavior include access to a tangible item (food or a favorite toy), attention from others (positive reinforcement), escape from a demand or an aversive stimuli (negative reinforcement), or sensory or other internal stimulation (automatic reinforcement) (41). By understanding the function of the behavior problem, parents learn to change their usual response in order to teach the child a more appropriate behavior (42). For example, a child may learn that a tantrum will result in escape from a routine demand (e.g., household chore). In such a case, the parent can be taught to (1) ensure the child is not allowed to escape from the routine demands, and (2) implement strategies to promote compliance (e.g., a reward for completing chores).

COMPONENTS OF PARENT TRAINING

Clinicians can now choose from one of several well-established, structured PT programs, including Webster–Stratton's Incredible Years (36), Kazdin's Parent Training (9), Sanders' Triple P-Positive Parenting Program (43), and Eyberg's Parent–Child Interaction Therapy (34) (see Table 6.2.4.1 for key features of commercially available evidence-based PT programs).Although there is variability across these programs in the targeted age range and use of particular behavioral management strategies, common components include *Assessment*, *Psychoeducation*, *Prevention Strategies*, *Consequences*, *Generalization*, *and Maintenance*.

Assessment

As with any intervention, treatment should be initiated after completion of an

assessment that provides an understanding of the child, family, and broader systems in which the child operates. Multimodal (parent, teacher, other caregiver), multimethod (interview, observation, rating scales) assessment will provide the widest range of information that can be used in treatment planning (95). Information gathered from multiple informants is preferred, as perspectives between parents as well as parents and teachers are often divergent (96,97).

Child and Family History

Information about the child should include collation of the child's development, including prenatal/postnatal complications, medical conditions that may affect the child's development or family functioning, as well as educational history, including special educational services. This information provides a foundation for guiding the family on the application of PT strategies. For example, compliance to commands is clearly tied to the child's receptive language (RL), with an RL threshold of 12 to 18 months required for the child to understand simple, one-step commands. Thus, if a child is identified as having notable developmental delays, family expectations regarding the child's ability to understand and comply with commands will need to be adjusted.

Family history, including psychiatric conditions in immediate and extended family, as well as current medical conditions in family members that may affect caregiving should be evaluated. Individuals involved in caregiving and the network of caregiving (mother, father, extended family members, other caregivers) will inform the family support structure and *who should be included* in treatment planning and implementation. For example, it may not be effective if the parent attending PT is not the primary caregiver for the child. Knowledge of the family structure may also help identify barriers to the application of PT strategies. For example, although the mother may be the primary caregiver, she may be unable to attend sessions due to her work schedule. In such a case, the best option may be to suggest that the grandmother attends the PT sessions. This arrangement could work if the grandmother is able and willing to relay information and implementation plans to the primary caregiver. This solution follows from the principle that, whenever possible, it is strongly preferred that the same caregiver attends each session to ensure continuity.

Current Parenting Practices

Assess the use of current parenting practices, including parental perception of strategies that work versus the strategies that do not work. This will identify what approaches will be new to the parent versus those that may be part of the parent's repertoire. Even techniques that are in a parent's repertoire, however, may need modification. For example, many parents report they have tried time out and are convinced that it does not work. In many instances, however, parents misapply time

out (e.g., ending the time out while the child is still upset; conducting time out in front of the television; using time out for an escape-maintained behavior). Effective PT involves educating parents about the use of new techniques and correcting ineffective application of particular strategies.

A focus of the assessment also should be on general parenting perspectives: Is the parent overly harsh (oriented to the authoritarian parenting approach, with an emphasis on punitive discipline strategies) or permissive (appropriate warmth in the parent–child relationship, but ineffective limit-setting and inadequate follow-through with consequences). It may also be informative to discuss the parental understanding of what is "driving" the child's behavioral problems. This discussion may delve into parental perceptions on locus of control (LOC), which is the degree to which the parent feels he or she has the ability to influence the child's behavior and development. Parents with an *internal* LOC acknowledge their impact on the child's behavior. Prior to initiating treatment, these parents may recognize their role in the child's behavior (e.g., "I know I don't follow through"). Conversely, a parent with an *external* LOC may attribute the child's behavior to environmental or biologic factors, with the implication that the parent has little influence on the child's behavior. Research suggests that an internal LOC is associated with higher maternal esteem, parental satisfaction, and fewer child behavioral problems (98–100). Implementation of PT strategies may be especially challenging with parents who describe feeling like the child's behaviors is due to external circumstances (e.g., "he was born that way," "he's just like his father," "it doesn't matter what I do, nothing works"). By contrast, parents who feel responsible, but *at a loss* on how to manage their child's behavior, may be more open and motivated to learn and implement PT techniques.

Topography Target Behaviors

Identification of target behaviors and function of those behaviors can occur through informal discussion with the family, parent ratings, and behavioral observations. Initial discussion should include delineation of the target behaviors that the parent hopes to address in treatment. The parent should be guided to describe the problems in behavioral terms: frequency of occurrence, duration, amplitude, actual appearance of the behavior, immediate aftermath, and impact on the family. These descriptions of behaviors promote a common understanding of the child's target problems and provide useful information on severity. For example, tantrums that occur one to two times a week lasting 5 minutes would be less severe than four to five tantrums per day each lasting 30 minutes. Tantrums that involve throwing objects, property destruction, or self-injurious behavior would be more severe than tantrums characterized by yelling and screaming. Parents may describe feeling on "pins and needles" in the immediate aftermath—apprehensive that the child may "go off again." Frequent and severe tantrums in a child may lead to reluctance to set limits in an effort to avoid future outbursts.

TABLE 6.2.4.1

EVIDENCE-BASED PARENT TRAINING PROGRAMS FOR DISRUPTIVE BEHAVIOR

Program	Format	Target Age	Key Components	Clinical Populations
Defiant Children (DC) (35,44–48)	Individual: Ten 1-hr sessions Group (6–10 families): Ten 2–2.5 hr sessions	2–12	*10-Step Program:* *Step 1*—Why children misbehave *Step 2*—Attending to appropriate behaviors *Step 3*—Increasing compliance and independent play *Step 4*—Implementing sticker and point charts *Steps 5 and 6*—Time out *Step 7*—Targeting behavior in public places *Step 8*—Targeting school behaviors *Step 9*—Handling future problems *Step 10*—Booster session Strategies: psychoeducation, positive attention, positive reinforcement, planned ignoring, compliance training, token economy systems, time out, generalization, and maintenance	• ODD • CD • ADHD • ASD • Juvenile-onset BD • Aggressive behavior • Mild ID • Tourette syndrome • Postdivorce adjustment
Helping the Noncompliant Child (HNC) (49–53)	Individual: Eight to ten 60-90 min sessions	3–8	*Differential Attention (Phase I):* • Promote positive parent–child relationship • Increase social attention • Ignore minor inappropriate behaviors *Compliance Training (Phase II)*: • Use direct, concise instructions • Set appropriate consequences for noncompliance	• ODD • ADHD

			• Establish "standing rules" • Implement techniques outside the home Strategies: positive attention, positive reinforcement, planned ignoring, compliance training, time out, generalization, and maintenance	
Incredible Years (IYS) (36,54–65)	*IYS for Parents:* Groups of 8–12 parents BASIC: • Baby: 9–12 sessions • Toddler: 12 sessions • Preschool: 18–20 sessions • School-Age: 12–16+ sessions ADVANCED: 9–12 sessions SCHOOL READINESS (adjunct to Preschool): 4–6 sessions *IYS for Teachers*: Groups of 12–14 teachers *IYS for Children*: Groups of 5–6 children; 18–22 sessions	Baby/Toddler: 0–2.5 Preschool: 3–5 School Age: 6–12 Teacher: 3–8 Classroom: 3–8 Small Group: 4–8	*IYS for Parents:* BASIC • Enhance positive interactions • Establish proactive discipline ADVANCED • Enhance effective communication • Manage anger and depression • Promote problem solving • Support networks/teacher partnerships *IYS for Teachers*: • Establish proactive discipline • Promote positive teacher–student relationships • Promote social skills and emotional regulation • Promote positive teacher–parent partnerships *IYS for Children*: • Increase emotional, social and academic competencies Strategies: psychoeducation, prevention, positive attention, reinforcement, planned ignoring, compliance training, house rules, time out, token economy	• ODD • ADHD • CD • At risk for CD, delinquency and substance abuse • Aggressive behavior • Anxiety disorders • Depression • High-risk populations (low income, abuse/neglect) • Risk reduction (abuse/neglect) • Foster parents • Postdivorce adjustment • ASD
Parent–Child Interaction	Individual: Twelve to	2–8	*Phase 1 (Child-Directed*	• ODD • CD

Therapy (PCIT) (25,27,34,66–80)	fourteen 60–90 min sessions Group: 3–6 families Sixteen 1.5–2 hr sessions		*Interaction):* • Improve the quality of the parent–child relationship • Use the PRIDE Skills during “special time”: Praise, Reflection, Imitation, Behavioral Description, Enjoyment *Phase 2 (Parent-Directed Interaction):* • Establish a structured and consistent approach to discipline Strategies: positive attention, planned ignoring, compliance training, time out, generalization and maintenance	• ADHD • Posttrauma • Risk reduction (abuse/neglect) • Separation anxiety • Depression • SIB • Postdivorce adjustment • ASD
Parent Management Training (PMT) (9,81–85)	Individual: Twelve to sixteen 45–60 min sessions	2–14	*Four components:* 1. Conceptualize how to change social, emotional and behavioral problems 2. Implement techniques that follow from that conceptual view 3. Develop parent skill through active methods of training 4. Integrate assessment in treatment decision-making Strategies: psychoeducation, positive reinforcement, compliance training, time out, planned ignoring, token economy	• ODD • CD • ADHD • TS • Aggression • ASD • ID • LD
The Community Parent Education Program (COPE) (86–88)	15–25 families Six to eight 2-hr sessions	3–18	• Encourage positive behavior and improving parent–child relationships (positive reinforcement) • Balance family relationships	• ODD • ADHD

			• Avoid conflicts • Manage transitions • Increase compliance • Improve self-regulation • Decrease antisocial behavior • Advanced strategies: set up point systems • Coordinate child management plans Strategies: positive reinforcement, planned ignoring, time out, token economy, compliance training, generalization and maintenance	
Triple P-Positive Parenting Program (24,43,89–94)	5 levels of intervention: *Level 1 (Universal):* Population-based informational media campaign *Level 2:* Individual: One to two 20 min sessions Group: 3, 90-min seminars *Level 3 (Primary Care):* Children with specific, mild to moderate behavioral issues *Level 4 (Standard):* High-risk children Individual: Ten 1 hr sessions Group-: Five 2-hr sessions with 10–12 families Self-directed:	2–16	*Five core positive parenting principles:* 1. Ensure a safe, engaging environment 2. Create a positive learning environment 3. Use assertive discipline 4. Have realistic expectations 5. Take care of oneself as a parent Strategies: positive attention, behavioral contingencies, token economy, compliance training, planned ignoring, time out	• ODD • ADHD • CD • High-risk populations (low income, maternal depression, relationship conflict, single parent) • Risk reduction (child abuse/neglect) • ASD

	10 sessions *Level 5, Enhanced:* children with complex behavioral issues and concurrent family issues	

ADHD, attention-deficit hyperactivity disorder; ASD, autism spectrum disorder; BD, bipolar disorder; CD, conduct disorder; ID, intellectual disability; LD, learning disability; ODD, oppositional defiant disorder; SIB, self-injurious behavior; TS, Tourette syndrome.

Finally, discussion of where and with whom the behavioral problems occur can be informative when planning treatment. The presence or absence of behaviors in specific settings or with particular people also can inform whether PT is the appropriate course of treatment. For example, treatment may be difficult with a parent who reports that behavioral problems are only present at school. If this an accurate report, it may be that the teacher needs guidance on behavior management. In some cases, disruptive behaviors are occurring both at school *and* home, but the parent may be underreporting and perhaps has become tolerant of the child's behavior. In such cases, parents may need help to recalibrate appropriate behavior before initiating PT. Particularly challenging cases involve parents who underreport problem behavior in the home and have little motivation to modify his or her parenting approach. A positive indicator for PT is when a parent reports behavioral problems in the home that are less prominent at school. This suggests that the child has some ability to regulate behavior at school and may prompt the parent to seek help in managing the child's behavior.

Assessment Methods

Behavioral Observation

Direct observations by parents, teachers, and clinicians permit prospective data collection rather than reliance on recall of past events. Standardized observational approaches have been developed to examine the child's behavior and child–caregiver response in semi-structured parent–child interactionscenarios. For example, the Dyadic Parent–Child Interaction Coding System uses a structured, 15-minute observation with three conditions: child-led play; parent-led play; clean up to ascertain rates of noncompliance, parent use of inappropriate discipline strategies, as well as the general parent–child interactional style (e.g., disengaged, overly directive or harsh, passive with limit-setting, and level of warmth) (101).

Following an ABA framework, observation of child behavior also may take the form of a functional analysis or descriptive functional assessment (102). Functional analysis involves direct observation and manipulation of environmental events that

precede (antecedents) and follow (consequences) the behavior of interest in the clinical setting in order to determine the function maintaining the behavior (103). Thus, functional analysis identifies the purpose of the disruptive behavior in a controlled setting. However, this approach requires specialized training, is time consuming, and the experimental conditions may not completely mimic naturalistic settings (102). For these reasons, functional analysis is not common in clinical practice (104).

Descriptive functional assessment uses caregiver report and observation in naturalistic settings (e.g., classroom or home) to determine the purpose or function of the behavior and the environmental response that is maintaining the behavior. In so far as this method relies on information from the natural environment, caregivers can be taught to record observations and contribute to the interpretation of findings and development of specific strategies (105,106). Descriptive functional assessment is less expensive and time consuming than formal functional analysis and thus is easier to utilize in clinical practice (107,108). To date, however, descriptive functional assessment has not been carefully studied. Indeed, systematic reviews have identified only a few studies, and interventions based on this assessment method may be less successful than those based on functional analysis (109).

Informant-Based Methods

The Child Behavior Checklist (CBCL) is a well-established, reliable, and valid parent rating covering a wide range of internalizing and externalizing behaviors. There are two versions of the CBCL: The preschool checklist (CBCL/1½–5) contains 100 questions for children aged 18 months to 5 years, and the school-age version (CBCL/6–18), which contains 120 questions for youth aged 6 to 18 years. There are also CBCL versions for teachers, daycare providers, and a youth self-report (110,111). Responses are recorded on a Likert scale: 0 = Not True, 1 = Somewhat/Sometimes True, 2 = Very True/Often True. Items are summed to produce subscale and syndrome scores, internalizing and externalizing problem scales, as well as a total score derived from all questions. Each syndrome, problem scale, and the total score yields a T score (population mean of 50 and a standard deviation of 10). Scores of 65 or greater on a given scale are considered clinically significant.

The 36-item, parent-rated Eyberg Child Behavior Inventory (112) (ECBI), and the 38-item, teacher-rated Sutter–Eyberg Student Behavior Inventory (113) (SESBI), focus on disruptive behavior problems. The SESBI contains two factors—oppositional behaviors and attention problems—that may be used to track these behavior categories in the classroom.

The Behavioral Assessment System for Children (114) (BASC) is a multi-method, multidimensional approach to evaluating behavior and self-perception of children ages 2 years 6 months to 18 years. It includes teacher (TRS) and parent (PRS) rating

scales, a self-report of personality (SRP), a structured developmental history (SDH), and a student observation system (SOS). The PRS is used to measure both adaptive behavior and behavior problems in the community and home setting. Parents or caregivers can complete forms at three age levels—preschool (ages 2 to 5), child (ages 6 to 11), and adolescent (ages 12 to 21). The PRS contains 134 to 160 items and uses a four-point scale ranging from "Never" to "Almost Always." The TRS measures adaptive behavior and behavior problems in the preschool or school setting. Teachers can complete the 100 to 139 items depending on age level (preschool [ages 2 to 5], child [ages 6 to 11], and adolescent [ages 12 to 21]).

The Disruptive Behavior Rating Scale–Parent Version (115) (DBRS-PV) is a brief (26-item) rating scale used to assess inattention, hyperactivity–impulsivity, and oppositional defiant behavior among school-aged children. The DBRS is an expanded version of the Attention-Deficit Hyperactivity Disorder (ADHD) Rating Scale–IV (116) (ADHD-IV). Parents rate how often symptoms occurred in the past 6 months using a four-point Likert scale. The DBRS-PV also has sections assessing the degree to which the symptoms impair the child.

The Swanson, Nolan, and Pelham-IV (SNAP-IV) is a 90-item parent- or teacher-report designed to measure behavior problems in children for children 5 to 18 years (117). The first 46 items cover symptoms of ADHD, ODD, and CD.

Psychoeducation on the Principles of PT

Treatment can begin once a family has been deemed appropriate for PT: the child exhibits target disruptive behaviors, a caregiver can consistently attend weekly clinic appointments and is ideally motivated and open to modifying his or her parenting approach. As parents often describe the child's disruptive behavior as "coming out of nowhere," PT often begins with psychoeducation on the reasons why problem behaviors occur.

Why Children Misbehave

Russell Barkley's manual, *Defiant Children* (35), presents four major factors that contribute to the child's misbehavior: (a) *child psychological characteristics* (e.g., child temperament) and *developmental challenges*; (b) *parental characteristics* (i.e., mental, physical health); (c) *situational consequences* that, over time, teach the child that disruptive behavior allows escape from undesirable tasks; and (d) *family stressors* (financial, marital difficulties). Individually and collectively these factors may increase the likelihood of parent–child conflict and hinder the parent's ability to manage the child's behavior.

Young children may have difficulty communicating everyday concerns, wants, and needs. This is clear for children with developmental delays. Even children who do

not have developmental delays may have difficulty “using their words” when frustrated or angry. Disruptive behaviors, such as temper outbursts, become inappropriate, but ironically effective ways for the child to communicate needs and demands. Many PT programs encourage parents to consider what the child maybe trying to communicate through the disruptive behavior. A tantrum could be saying “This is too hard.” Screaming could mean “Leave me alone.” Hitting could be communicating “That’s mine. Give it back.”

ABA begins with the assertion that the child’s disruptive behavior is not a random occurrence. Parents may be eloquent in their description of the child’s behavioral problems, but less able to describe the events and situations that increase the likelihood of the behavior. Faced with the occurrence of behavioral problems that they do not understand, parents may inadvertently respond in ways that reinforce the child’s misbehavior. The Antecedent–Behavior–Consequence (ABC) model breaks down the sequence to identify the environmental circumstances that may provoke the behavior (antecedents) and the parental responses that maintain the behavior (consequences). This, in turn, facilitates a better understanding of how to then manipulate the environment by modifying the antecedents that trigger and consequences that maintain a behavior.

Education on Child Development

In PT, parents are encouraged to consider the child’s development and to keep expectations in accordance with the child’s abilities. Behavioral difficulties may emerge if a parent holds unrealistic expectations about the child’s skill level. For example, a child with impaired receptive language skills would affect the child’s understanding of verbal commands and predictably reduce compliance if commands are too complex. Conversely, parents may have lowered expectations about a child’s abilities and refrain from placing appropriate demands on the child. Although lower demands on the child may reduce noncompliance, lower demands may also interfere with the acquisition of new skills and the regular performance of current skills. Thus, effective PT finds a balance between increasing parental demands or expectations for the child at a pace that fits with the child’s development.

Effective Communication

Parents can avert some behavioral problems by using clear language to convey expectancies and consequences to the child. The goal is to move from vague threats or promises (e.g., “You need to behave and listen or you’ll be in trouble.”), which may confuse the child, to clear contingencies (e.g., “You need to put your toys away before you can go play outside”). Clarity in verbal direction reduces the likelihood of misunderstanding about expectations and the consequences if the child does not comply. An important principle here is to establish the behavioral expectancy before

the behavior occurs and not in response to it.

Consistency and Predictability in Behavioral Management

A final treatment consideration to impart to parents early in PT is the importance of consistent implementation of behavior management strategies. Inconsistency aligns with the behavioral principle of "intermittent reinforcement," in which the behavior is reinforced some—but not all the time. Intermittent reinforcement increases the occurrence of the behavior and teaches the child that the persistence of the challenging behavior will eventually be reinforced. Consistency is not always easy, but it is important. In order for any behavioral management strategy to be effective—following through to completion is key to making it work. In time, the child learns that having a tantrum will no longer result in escape from a routine expectation or that screaming will not work to get the parent's attention. This predictability in parental response sets the stage for a new behavioral expectation.

Prevention Strategies

Prevention (or antecedent management) strategies are designed to avert the occurrence of behavioral problems by modifying the antecedents or triggers of the behavior problems. Parents commonly use prevention strategies for young children, such as putting a baby gate on a staircase to prevent the child from falling down the stairs or putting locks on cabinet doors to block access to household cleaners.

Prevention strategies call on parents to think ahead in order to identify a predictable behavioral sequence (e.g., when told "no" [antecedent], the child has a tantrum). Once the pattern is identified, the parent can implement a strategy to eliminate or modify the antecedent of that behavior. Common antecedent management strategies include the following:

Controlling the Environment

For safety concerns, a parent might place locks on drawers or cabinets that hold dangerous chemicals. To minimize property destruction, a parent may place breakable items from reach. Valuable items may be put in a safe location. To prevent the onset of disruptive behavior, a parent might put certain items "out of sight" (e.g., cookies, a certain toy prone to cause fights between siblings). These environmental controls decrease the likelihood of the child engaging in potentially harmful, dangerous, or disruptive behaviors.

Creating Daily Structure and Routines

Increasing predictability in the child's daily routine (e.g., getting ready in the

morning, bedtime routine) can avoid instances in which the child might protest in response to a new demand or transition from a preferred to a nonpreferred activity.

Providing Choices

This can be an effective replacement for saying “no” in everyday situations that trigger misbehavior in the child. Choices create the illusion that the child is in control of decision-making, but the choices are defined by the parent. For example, instead of telling a child “No, you cannot have ice cream for breakfast,” the parent can provide the choice “Would you like eggs or cereal for breakfast.”

Consequences

PT also includes several consequence-based techniques, including positive social attention, planned ignoring, differential reinforcement, behavioral contingencies, token economy systems, compliance training, and time out.

Positive Social Attention

The goal of positive social attention is to reverse the negative (and cyclical) parent–child interaction described by Patterson (21). This involves an increase in parental awareness and acknowledgment of the child’s appropriate behaviors. Specific positive social attention strategies include the use of praise, “catching the child being good,” and engaging in child-led play.

Praise involves overt verbal expression to the child following the performance of positive behaviors. Although common praises include “great job,” “way to go,” or “nice job,” parents should also be encouraged to label exactly what the child is doing well (e.g., “Great job putting the dish in the sink”). The use of labeled praise can be especially powerful to highlight “positive opposite” situations. For example, if a child frequently hits his sibling, praise would be used to label moments when the child keeps his hands to himself. If loud screaming in the home is a problem, a parent would be encouraged to praise the positive opposite behavior “thank you for using an inside voice.”

Catching a child being good is another example of using labeled praise to point out the moments that the child is engaging in appropriate behavior. A parent may target specific times of the day (e.g., the morning routine) or certain behaviors (e.g., sharing toys with a sibling; compliance to commands) that have been challenging. Parents can also be encouraged to identify and declare, through the use of praise, instances when the child is engaging in appropriate behavior.

In order to promote positive parent–child interactions, the parent is encouraged to follow the child’s lead in a brief 5- to 15-minute “child-led play” session. In addition to letting the child lead the play, the parent is reminded to avoid giving

commands, asking questions, or setting limits, which take the lead away from the child and set up potential conflicts. Parents should take every opportunity to provide positive attention to the child by describing the child's activities, praising appropriate play, and reflecting appropriate child vocalizations. This play situation is a staple for many PT programs (PCIT, Barkley's Defiant Children). Selected activities depend on the age and interest of the child but may include puzzles, play doh, legos, and arts and crafts.

Planned Ignoring

The partner to providing positive social attention to the child is deliberate ignoring of inappropriate behaviors. Common targets for planned ignoring are socially maintained (attention-seeking) behaviors such as tantrums and whining. Planned ignoring requires complete disengagement (silently turning away, no eye contact or directed affect, no language directed toward the child) until the behavior subsides. When the behavior stops, the parent re-engages with the child. Planned ignoring is best applied when the child's behavior is not dangerous to the child, to others, or to property. Behaviors involving aggression, self-injury, or property destruction are more difficult to ignore and may require the parent to intervene in order to reduce harm. A challenge with the implementation of planned ignoring is the child's behavior often escalates to include behaviors that cannot easily be ignored before it eventually decreases. Parents often need guidance on how to handle situations in which the child engages in potentially dangerous or destructive behaviors. For example, if a child who is being ignored by his parents begins to throw objects, the parent may be coached to continue the use of planned ignoring while physically redirecting the child to a different room. Otherwise, parental anxiety about the child's increasingly provocative behaviors may lead some parents to attend to the child and inadvertently reinforce the behavior.

Differential Reinforcement

This approach combines positive social reinforcement and planned ignoring in order to show that positive parental attention will be received only when the child engages in appropriate behavior. Negative behaviors will no longer receive attention (via the use of planned ignoring). For example, a child who initially makes a request (e.g., for a favorite toy or snack) but does so in a demanding manner would be ignored by the parent until the child's negative behavior subsides. Only when the child asks for the item in an appropriate manner would the parent attend and respond to the child. To bolster this concept, the parent can also praise other instances that the child spontaneously requests items in an appropriate way (e.g., "I like how you asked for the snack in a nice way. I would be happy to give it to you.").

Behavioral Contingencies

Sometimes referred to as "behavioral contracts," behavioral contingencies are designed to create clear expectations for the child about a target behavior and its consequences. A common format for a behavioral contingency is "If/First___Then___" statements. This involves a counterbalance of a specific demand or behavior with a reinforcer ("if you finish your dinner, then you can have ice cream"), natural positive consequence ("first you put your coat on, then you can go outside"), or punishment ("if you hit your sister, then you will go to time out").

Another version of a behavioral contingency is the implementation of a "house rule." This involves explicitly stating that a particular behavior (e.g., hitting a sibling) will be met with a predetermined consequence (e.g., time out or loss of a privilege). Strengths of behavioral contingencies and house rules are twofold. First, they provide a clear understanding to the child about what behavior is being targeted and what the consequence will be for engaging in that behavior. Second, they establish the rules "ahead of time"—which avoids bickering over what the child may perceive is an arbitrary consequence. This sets up an opportunity for the child to contemplate whether or not to engage in a target behavior because, assuming the parent follows through, the child knows what the ramifications will be.

Token Economy Systems

An expanded version of a behavioral contingency is a token economy system, often implemented as a point or a sticker chart. The child earns points or stickers for engaging in targeted behaviors. Points are accumulated and then can be exchanged for preferred items (access to a favorite toy or preferred activity). Weekly allowance follows this principle, in that a child is required to complete a set number of chores in order to earn a predetermined amount of money. Token economy systems provide an opportunity for the parent and child to work collaboratively to define the target behaviors as well as the desired rewards to be exchanged for the tokens. This collaborative effort promotes compromise between parent and child and fosters engagement on the child's part.

Compliance Training

Teaching children how to comply with commands the first time given starts by teaching a parent how to deliver an effective command: one that is direct, simple, one step, and given only one time. The goal is to establish for the child the importance of immediate compliance with a command to decrease occurrences of escape from the demand. These steps avoid common errors such as repeating a command multiple times before having the child comply, providing a command that is too complex (e.g., multistep), and giving vague instructions or indicating that compliance is optional,

such as giving a command with statements such as, “Would you mind … ?” “How about you …,” or “Let’s do ….” Once an effective command is given, parents are taught to follow through, in some cases with the use of physical prompting or guidance, to ensure the child completes the demand. Parents are also coached to provide immediate praise as the child completes the command.

Time Out

Time out is a form of planned ignoring where the child is removed from all reinforcing stimuli. Time out can be a very effective approach to targeting challenging, persistent behaviors. Unfortunately, parents often make errors in implementation that render the strategy ineffective. An important component to the effective use of time out includes restricting its use to one or two target behaviors at a time. This helps promote predictability for the child in terms of which behaviors will result in a time out. As time out is more formally known as “time out from reinforcement,” parents also must ensure that time out is located in a safe, distraction-free area—not on the couch in front of the television or in the bedroom where the child has free access to toys. In addition, the parent deliberately ignores the child during the time out, thus minimizing the amount of attention (positive or negative) that the child receives while in time out. Parents should choose a predetermined minimum amount of time that the child is to stay in time out. Once the predetermined amount of time has passed and the child is seated quietly (and for the child who is in time out for noncompliance, is willing to complete the command), the time out is over. This sequence avoids the problem of the child “completing” the predetermined time (e.g., 5 minutes) while the child is still very agitated, and thus likely to re-engage in the disruptive behavior. A final challenge involves situations where the child is unwilling to stay in time out. PT programs vary on how this issue is addressed such as using a backup time-out room or removal of a predetermined privilege if the child refuses to sit or stay in time out.

A Note on Spanking

Parents may report some success with physical punishment as a way to stop problematic behavior. There is evidence, however, that spanking is ineffective for reducing disruptive behavior. In fact, physical punishment can lead to increased aggression, antisocial behavior, and physical injury (118). For parents who use spanking as a discipline strategy, a nonjudgmental discussion on alternative approaches along with psychoeducation on the potential ramifications of physical punishment is warranted.

Generalization and Maintenance

A final component of many PT programs considers the strategies needed to promote skill generalization to other contexts and to maintain treatment gains over time. The goal of generalization is to increase the likelihood that positive behavior change extends into different settings and contexts that may not have been initially covered in the PT program. Many parents need preparation on how to apply PT strategies in new situations when conditions vary. For example, although a primary target of treatment may be to improve compliance at home, improvements in compliance in public places, at school, and at family events is also important. Thus behavioral generalization involves the transfer of positive behavior change to situations other than the ones initially targeted in the PT program. Maintenance means that positive behavioral changes will continue even after the end of active treatment.

IMPLEMENTING PARENT TRAINING IN CLINICAL SETTINGS

Although evidence for the efficacy of PT abounds, meta-analytic studies examining moderators to treatment suggest certain clinical subpopulations are less likely to show positive response to treatment. Poor treatment response has been found to be related to low family income and, to a lesser degree, related to low parental education/occupational status and maternal psychopathology (119,120). Other potential moderators, of modest effect, involve including the child in treatment and providing treatment in an individual (vs. group) format (13,121). PT components associated with positive response include in vivo practice with the parent's own child, teaching skills related to emotional communication (e.g., active listening, reducing negative communication), teaching parents to interact positively with their children, and an emphasis on consistent discipline (10).

When initiating PT, parents may initially struggle to understand why they are being asked to attend treatment when their child has the behavioral problems. Indeed, some clinicians may raise the same question. Some parents may also silently wonder if their need for PT implies that the child's behavior is the parent's fault. It is often useful to address these concerns up front. For example, it can be noted that children with prominent disruptive behavior require the application of specific parenting techniques that most other children do not require. The easiest contrast is if the family has multiple children—and how similar parenting strategies may work with one child, but not another. Therapists should also reinforce the notion that, because parents are on the "front line" dealing with the child's behavioral problems, they are attending treatment in order to become the agent of change for the child's behavior. A positive rephrasing of this principle is that the therapist is providing the parent with the skills to change the child's behavior. Finally, teaching parents strategies to manage child behaviors increases opportunities for the parent to implement the intervention strategies across multiple settings (e.g., home, the grocery store, the playground) and contexts (e.g., morning routine, homework, mealtimes, bedtime) and

to use the tools learned in treatment to address future behavioral problems. This discussion is all about the delicate balance of engaging the parent in the treatment while at the same time avoiding the suggestion that the parent is to blame for the child's disruptive behaviors.

PT involves teaching behavior management strategies that have been proven to reduce disruptive, noncompliant behaviors in children across a wide age range. The programs listed in Table 6.2.4.1 have solid empirical support. Applying a treatment manual into clinical practice, however, can be challenging. Successful implementation occurs when treatment systematically introduces parents to a range of techniques designed to shift the balance of negative parent–child interactions to positive. Although each program in Table 6.2.4.1 includes a range of strategies that have been effective, not every strategy fits with every child and parent. When it comes to specific PT techniques, what works for one parent and child dyad may not work for another. The goal is to tailor each of the strategies to fit the child and family and to equip the parent with the tools that will work for their family circumstances.

CHAPTER 6.2.5 ■ PSYCHODYNAMIC PRINCIPLES IN PRACTICE

RACHEL Z. RITVO AND MICHAEL SHAPIRO

HISTORY

The monumental work of Sigmund Freud grew out of a broader historic and epistemic context. The term *dynamic* in the late 19th century as used by Leibniz, Fechner, and the renowned neurologist, Hughlings Jackson, referred to changing states of consciousness and physiologic processes, as opposed to static, anatomic structures. Dynamic included a concept of mental energy. It implied functional rather than fixed organic impairment. In the 20th-century dynamic psychiatry—with its emphasis on the patient's subjective experience, the workings of unconscious psychological processes, and the patient's unique inner life—was contrasted with *descriptive* psychiatry, which strove to categorize patients according to observable behavior. Gabbard (1) describes more recent and wider uses of the term *dynamic* to include newer theories and research such as the "deficit model," object relations theory, attachment theory, and the inclusion of a biopsychosocial formulation which incorporates contemporary advances in neuroscience and genetics.

Sigmund Freud was a research neuroscientist before he turned to the clinical practice of neurology and eventually psychiatry. Although he recognized that the research methods of his time did not allow for a full explication of the neuronal base of psychic events, he endeavored to keep his psychological theories consistent with biology. For instance, Freud conceptualized the mind as the interplay of excitatory (drive) and inhibitory (defense) phenomena. Greatly influenced by Darwinian theory (2), Freud sought to construct a developmental framework for his psychology, an approach that put the psychic phenomena of childhood in the spotlight and paved the way for child psychotherapy. Psychoanalytic psychology as a theory of adaptation of humans to our environment derived from these Darwinian roots. Modern neuroscience offers an opportunity to refine psychoanalytic theory. The growing field of neuropsychoanalysis seeks to integrate the latest findings from cognitive neuroscience with psychoanalytic observations to improve our understanding of the brain substrates of psychoanalytic constructs (3).

Psychodynamic psychotherapy of children began with Freud's publication in 1909 (4) of the case of "Little Hans," a 5-year-old boy with a phobia of horses. Freud's interest was in the centrality of childhood experience in shaping the adult psyche. Although he sought to "reconstruct" childhood experience from the analysis of adults, he encouraged his students to observe children for more direct evidence of infantile sexuality. It was in this context that Freud came to supervise the analysis of Little Hans by Hans' father.

Hermine Von Hug-Hellmuth was the first to undertake psychoanalytic therapy of children and adolescents. Her 1921 paper “On the Technique of Child-Analysis” (5) surveyed technical issues in the psychodynamic treatment of children that are still recognized as core issues to this day. She noted that the child does not come of his own accord. She advises against a judgmental stance or the giving of direct commissions and prohibitions. Hug-Hellmuth engaged the child in “talking over things together.” She introduced the use of an educational method founded on psychoanalytic knowledge. She examined the multiple ways in which work with children and adolescents differs from that with adults, including the complexities of the relationship between the analyst and the child’s parents. Her observation that the child’s spontaneous play could stand in the place of the verbal communications of the adult to reveal unconscious conflict was significant for the development of psychodynamic therapy with children. Further, she observed that fully conscious avowal of analytic understanding was not a prerequisite for therapeutic effect in children.

Hug-Hellmuth’s early death limited her impact on the field of child psychotherapy. Melanie Klein (6) and Anna Freud (7) emerged as the founders of child psychoanalysis. Klein coined the term play analysis, emphasizing the child’s play as equivalent to free association. Her methods encouraged early, deep interpretations and minimized the analyst’s contact with parents and teachers. She developed the position that through play interpretation, children could be analyzed just as adults. Klein extended Sigmund Freud’s theories about internal conflict to younger children, and even infants, maintaining that libidinous drives and fear of punishment are evident from an early age. Klein portrayed the experience of the infant as shifting between libidinal and aggressive impulses and experiencing oneself as “good” or “bad” in addition to experiencing the “good breast” that provides nourishment and the “bad breast” which is unavailable and abandoning. This paradigm formed the basis for Klein’s *paranoid–schizoid* position: paranoid referring to the fear of harm coming to the “good breast” (or good infant) and schizoid referring to splitting away the hated “bad breast” (or bad infant). The counterpart *depressive position* refers to the infant’s realization and subsequent horror and guilt that the “breast,” mother, and infant are whole objects and cannot be split into good and bad parts.

Whereas Klein continued to focus on interpretation in work with children, Anna Freud took another approach. Anna Freud’s long career, from the 1920s to her death in 1982, allowed for significant evolution in her ideas regarding psychodynamic treatment of children and adolescents. Trained as a teacher, she was interested in the “educative” functions of the analyst in working with children, rather than purely interpretive functions. Her contention was that young children could not handle deep interpretations because of their underdeveloped egos. Anna Freud’s work on ego mechanisms of defense (8) led to the development of defense analysis of children and adolescents. Her attention to observing the developmental process in children led her

to conceptualize interweaving lines of development (9).

The English psychoanalyst Donald Winnicott, who remained independent from both the Kleinians and the Freudians, brought a pediatrician's perspective to his work, particularly his experience of direct involvement with infants and their mothers. Winnicott was interested in how the infant developed a sense of self, a sense of reality, and a capacity for self-regulation. His work influenced Kohut's development of self-psychology (see below). Gifted at coining evocative terms for his novel concepts, Winnicott gave us: "good enough mother," "transitional object," "holding environment," and "false self." Winnicott is known for his aphorism "*There is no such thing as an infant*, meaning, of course, that whenever one finds an infant one finds maternal care, and without maternal care there would be no infant" (10).

John Bowlby (11–13) was a psychoanalyst who broke with mainstream child psychoanalysis in Britain and America by taking a strong empirical approach to studying psychoanalytic developmental constructs. His focus was on the direct observation of the behavior of infants and their caregivers through prospective studies of the effects of early attachment on relationships and on personality development. Attachment theory has bridged the gap between clinical psychodynamic theory and developmental psychology. In the early 21st century, of particular interest to attachment researchers has been the elucidation of the impact of attachment history on patients' capacity for *mentalization*, also referred to as *reflective functioning*, and defined as "the ability to take account of one's own and others' mental states in understanding why people behave in specific ways" (14). An example of treatments developed by drawing on this research is Bleiberg's Mentalization-Based Treatment of Adolescents (MBT-A) for emerging borderline personality disorder (BPD) (15).

Emigrant analysts fleeing the Holocaust brought this rich array of psychoanalytic thought to America. Child analytic training took root in the United States, allowing child psychoanalysts to play a major role in the training of child and adolescent psychiatrists throughout the mid- and late 20th century. A distinctly American therapeutic tradition also contributed to the field of dynamic psychotherapy with children, particularly play therapy. Homegrown American psychodynamic therapists such as Frederick Allen of the child guidance movement (16) and Carl Rogers, author of client-centered therapy (17), sought to counteract the impact of the American behaviorist tradition. Allen objected strongly to the behaviorists' belief that a child was born a blank slate who could be formed by parents into anything the parent wanted. Allen believed this behaviorist stance "created a distortion of a parent's sense of responsibility… [and a] failure to appreciate the nature of growth and the participation of both child and parent in the child's development" (16). Addressing the therapist/patient relationship, Allen regarded the child as a person in his own right, a human being with a capacity to change who should be respected as a an active participant in the therapy (16). The child's exercise of free expression, a here-and-now focus, and rapport in the relationship between patient and therapist were

emphasized as an American school of “nondirective” therapy developed through the work of Axline (18) and Dorfman (19).

PSYCHODYNAMIC PSYCHOLOGY

Psychodynamic psychotherapy aims at bringing about change in psychological processes that are largely unconscious but can be inferred from observable phenomena, such as actions or speech. The processes determining the inner world of subjective experience are of particular interest. The plethora of unconscious processes of which the human brain is capable allows for great diversity of focus for dynamic psychotherapy.

Psychodynamic therapy requires as a foundation a theory of the functioning of the unconscious mind and the internal experience of the individual as well as a theory of the psychological impact of human relationships.

In dynamic theory, the mind is not seen as a blank slate at birth but rather as endowed with the biologic potential to develop psychic structure given an adequate environment. *Internalization* denotes the process by which experiences with the external world, usually in the realm of relationships, form stable intrapsychic structures or capacities. Once a process is internalized it no longer requires an external stimulus for its function to be executed. *Identification*, the psychological process by which one individual becomes like another, is a familiar mechanism of internalization.

Unconscious psychological processes may be considered as primary determinants of the inner world of subjective experience. The individual’s total subjective experiential world, including thoughts, feelings, and fantasies, as well as perceptions of the external world, regardless of whether they accurately reflect the external world as viewed by another observer, has been termed *psychic reality*. The dynamic therapist attempts to grasp the patient’s psychic reality and convey to the patient an interest in understanding his experience of himself.

A primary tenet of psychoanalysis is *psychic determinism* (20), the principle that nothing in the mind happens by chance or in a random way. All psychic acts and events have meanings and causes and can be understood in terms of earlier psychic events. The mind retains experiences and is shaped by them. Conscious thoughts and overt behaviors provide observable clues to their underlying unconscious psychic determinants. A corollary hypothesis, *overdeterminism* or *multideterminism*, states that a psychic event (e.g., a symptom) is typically caused by more than one factor and may serve more than one purpose in the psychic framework. The multidetermined nature of symptoms provides the psychodynamic therapist with more than one way to approach a symptom.

The concept of multideterminism is further refined in dynamic theory by the observation that the multiple determinants of a particular observable psychic

phenomenon are frequently in opposition or *conflict* with one another. Psychodynamic theorists have identified several types of psychic conflict. *External conflict* denotes the conflicts that arise between the child and the environment, the consequent frustration demanding management by the child's psyche. External conflicts are most evident in early childhood when the infant or toddler has little internal restraint and struggles with the caretaker over such matters as bedtime or playing with an electrical plug. As prohibitions become internalized, the conflicts become *internal*. Not all conflicts are caused by prohibitions. Conflicts may arise between competing urges, thereby creating ambivalence. For example, conflicts arise between urges toward passive-dependence and active-mastery. An external conflict may or may not become a fully *internalized conflict*. An internalized conflict is conceptualized as continuing in the individual's psyche when environmental forces that triggered the initial internal conflict no longer exist.

Psychodynamic therapy capitalizes on the observation that human beings are psychologically changed by relationships with other human beings. Psychodynamic technique utilizes two aspects of human relationships to achieve its mutative effects, transference, and the real relationship.

Particular attention is paid to *transference*, the unconscious displacement onto the therapist of patterns of feelings, fantasies, attitudes, and behavior originally experienced in relation to significant figures during childhood. Additionally, transference is frequently used as a general term for the patient's attitudes and behavior toward the therapist and as such includes *externalizations*, which Anna Freud specifies as:

> … processes in which the person of the analyst is used to represent one or the other part of the patient's personality structure…. The child thus re-stages his internal (intersystemic) conflicts as external battles with the analyst, a process which provides useful material (9).

Brenner points out that the phenomenon of transference is not unique to the therapeutic relationship but rather "*every* object relation is a new edition of the first, definitive attachments of childhood" (21). In essence, psychodynamic theory proposes that psychologically significant relationships contribute to the individual's perceptions, thoughts, fantasies, feelings, attitudes, and behavior in all future relationships.

A portion of the therapeutic action of psychodynamic therapy rests in the experience of the *real relationship* with the therapist. The child even more than the adult has receptivity for new experiences. The psychodynamic therapist provides the child or adolescent with a new object for internalization. The therapist strives to cultivate specific qualities, some of which may be novel to the child. These include a respectful attitude toward the child, particularly toward the child's thoughts and

feelings, as well as the protection of the child's confidences from intrusion by parents or teachers. The therapist strives to be reliable and predictable in the arrangements made for meeting with the child (22). Most significantly, the psychodynamic therapist establishes a relationship with the child that is largely unilateral in its focus so that the events of the therapy evolve primarily from the child. Unlike the relationship with parents or peers, in which there is a necessary and healthy reciprocity, the focus on the child in the relationship with the psychodynamic therapist allows the internal world of the child to dominate their interactions (23). The therapist as an interested and thoughtful observer becomes a model for the child's development of the capacity for self-observation, a capacity termed *observing ego*. For children who have deficits in reflective functioning, the therapist's respect for the child's mental life and implied recognition that it is uniquely the child's is important in helping the child to develop this capacity.

Although the primary focus in the patient–therapist relationship is tipped toward the patient, psychodynamic theory does address the therapist's experience of this relationship. *Countertransference* refers specifically to intrapsychic conflicts stirred in the therapist by the patient. Generically, countertransference refers to all the reactions of the therapist to the patient or the parents, and is a valuable source of information about a patient's internal world, in addition to sometimes interfering with treatment (1). Marshall (24) operationalizes the definition of countertransference into two categories: (a) reactions arising from the therapist's unresolved internal conflicts; and (b) natural reactions to a patient's provocative behavior. Winnicott (25) dubbed this second-type *objective* countertransference, objective in the sense that virtually everyone would find the patient's behavior provocative. The challenge to the therapist when the objective countertransference is recognized is to construct a response that is both honest and therapeutic.

Treatment alliance and *working alliance* are terms used to refer to "all the factors that keep a patient in treatment and which enable him to remain there during phases of resistance and hostile transference" (26). *Resistance* is a conceptualization of the psychological mechanisms that cling to the intrapsychic status quo and seek to prevent change. In essence, resistance is a defense against affects, undesirable self-representations, or unwanted drive derivatives that are stirred and moved toward awareness by the therapeutic process. Inherent in the treatment alliance is the patient's awareness of internal difficulties and an acceptance of the need to be helped. Children with very fragile self-esteem may balk at entering into therapy because they cannot tolerate the recognition of their difficulties.

In child and adolescent treatments, the establishment and maintenance of the alliance are more complex than in adults because of the dependence on parents to bring the child to treatment. A positive alliance with the parents sustains the child's engagement in treatment even when the child's resistance is strong. Since parents can subtly oppose the child's wish to come to treatment or collude with the child's

resistance, the therapist must establish and maintain a working alliance with the parents sufficient to keep the therapy going. Novick and Novick (27) reach beyond this minimum. They view the therapeutic alliance with the parents as a transformative task "designed to help parents gain or regain some feeling of competence as parents and love for their child as a separate person."

Defense mechanisms are unconscious, automatic, psychological processes. The individual does not consciously choose to institute a defense; however, an individual can learn to recognize defensive activity as it occurs (28). Anna Freud's classic *The Ego and the Mechanisms of Defense* (8) enumerated several patterns of defense already in the analytic literature: regression, repression, reaction formation, isolation, undoing, projection, introjection, turning against the self, reversal, and sublimation. To these she added: turning passive to active, denial, intellectualization, displacement, identification with the aggressor, and altruistic surrender. Following that publication, effort was devoted to developing a comprehensive catalog of defense mechanisms. Clinical observation eventually led to the conclusion that any aspect of ego functioning may be used in the service of defense and the attempt to delineate a comprehensive list of specific mechanisms was impossible and potentially misleading in its reductionism. Nonetheless, children use certain mechanisms with sufficient frequency that it is of value to psychodynamic child therapists to be able to recognize them in the clinical situation (Table 6.2.5.1).

Controversy exists both within dynamic child psychiatry and between dynamic and descriptive psychiatry regarding the degree to which defensive activity and internal conflict involve such *autonomous* ego functions as perception, motility (walking, eye–hand coordination), intention, intelligence, logical thought, speech, and language. Autonomous ego functions are conceptualized by Heinz Hartmann (30) to be relatively resistant to disturbance by intrapsychic conflict. It is clear that many disturbances in this area have their origins in individual differences in brain functioning. However, it is also clear from clinical material that in many children and adults, these presumed autonomous functions are impacted by conflict and defense. This is no surprise to psychiatrists familiar with the way cognitive function is impaired by defensive denial. The challenge to the child and adolescent psychodynamic therapist is in the differential diagnosis. Psychological testing by a professional skilled in elucidating this distinction can be very useful.

SCHOOLS OF PSYCHOANALYTIC THOUGHT

The 20th century witnessed the growth of an extensive body of psychoanalytic observations and theories from which three major schools of psychoanalytic thought emerged: ego psychology, object relations theory, and self-psychology. The dawn of the 21st century has seen the emergence of mentalization-based approaches that draw on the findings of the other schools but develop a new focus. Practitioners often

specialize in one school's approach but borrow from the others depending on the features of the clinical situation.

EGO PSYCHOLOGY

Freud realized that a conceptual tool was needed to provide a framework for clinical data and hypotheses about unconscious phenomena and subjective experience. He termed such a tool "metapsychology." Different models evolved as he strove to accommodate all his data. The most lasting of Freud's metapsychological frames is a structural theory, the *tripartite model*, which divides mental functions into *id, ego,* and *superego*. Ego psychology developed from this tripartite model.

TABLE 6.2.5.1

DEFENSES COMMONLY EXHIBITED BY CHILDREN IN PSYCHODYNAMIC THERAPY

Denial	The disavowal of intolerable external reality factors or of thoughts, feelings, wishes, or needs that are apparent to an observer
Displacement	The transfer of emotions, ideas, or wishes from the original object to a more acceptable substitute
Externalization	The attribution of internal conflicts to the external environment and a search for environmental solutions. In therapy, the person of the therapist is used to represent one or the other part of the patient's personality structure
Reaction formation	The adoption of affects, ideas, or behaviors that are the opposites of impulses harbored either consciously or unconsciously
Repression	The exclusion of unacceptable ideas, fantasies, affects, or impulses from consciousness or the keeping out of consciousness what has never been conscious. Repressed material emerges in disguised form in thought, speech, and actions
Suppression	The conscious effort to control and conceal unacceptable impulses. Suppression is the exception to the rule that defenses are unconscious processes
Somatization	The transfer of tension from drives or affects into disturbances of bodily functions or rhythms
Turning passive to active	The management of affects and impulses stirred by a passive experience with an active, more powerful "other" by playing out in action or story the active "other's" role. This includes the process of identification with the aggressor

From Edgerton J, Campbell RJ (eds): *American Psychiatric Glossary*. Washington, DC, American Psychiatric Press, 1994; Freud A: *The Ego and Mechanisms of Defense*. New York, International Universities Press, 1936; Freud A: *Normality and Pathology in Childhood: Assessments of Development*. New York, International Universities Press, 1965.

Id is a concept that encompasses the mental representations of the instinctual drives (31). *Drive* is a term applied to a stimulus arising within the individual that arouses the mind and incites mental activity. Drives may be thought of as genetically endowed motivational states. Commonly we think of these as urges, needs, wishes, and desires.

Feelings are internal stimuli very familiar to the average person. Because emotions arise from physiologic response patterns, they are an early, although in

psychoanalytic theory not primary, step in the pathway to arousal and mental activity. In psychoanalytic theory, affects serve a signal function triggering ego efforts to manage drives.

Classical Freudian theory works with a dualistic system of drives, an aggressive and a sexual drive. The sexual or *libidinal* drive includes affiliative and pleasure-seeking urges. A child who desires to be bathed by the parent and have his or her naked body admired is displaying a derivative of the libidinal drive. The pleasure the child takes from the sensuous experience of the water would also be a libidinal drive derivative. While aggression has primarily referred to hostile urges, contemporary analysts have extended it to include assertive, constructive behaviors directed toward mastery, ambition, and fairness (32). Because pleasures sought in response to libidinal drive inevitably run into some requirement for delay or other frustration in the real world, ego mechanisms must develop to regulate aggressive drives if libidinal drives are to be satisfied.

Ego includes all the mental capacities available to the individual for regulation of the internal milieu and adaptation to external reality. Ego's task is to optimize pleasure and gratification of wishes and needs while maintaining internal equilibrium, the health of the body, good relations with the external world, and peace with superego.

Ego is often defined in terms of its numerous functions such as cognition, perception, memory, motility, language, symbolization, reality testing, judgment, impulse control, affect regulation, internal representation, object relations, self-

observation, and defense (Table 6.2.5.2). Work with children requires examining each of these functions in the context of the child's age and developmental accomplishments. Therapy is aimed at facilitating the child's progressive development of mature ego functions so the child can better manage situations and internal conflicts that are causing symptoms.

Superego, the moral agency in the tripartite model, encompasses conscience, morality, critical self-observation, self-punishment, and upholding of personal ideals (34). Although available to consciousness as moral precepts and ideals, superego functions are predominantly unconscious. Superego is built out of the child's desire to please adults and the fear of displeasing adults and thereby losing their love and care. It grows from experiencing consequences in the physical and social world and from identification with the models of self-control and moral values presented by important adults. There is continuing development of a set of standards, *ego ideal*, epitomizing the individual's beliefs of what is right, good, or desirable. Superego can be effective in controlling behavior in conformance with this ideal only to the degree that ego capacities have developed to be deployed in thwarting and channeling unacceptable impulses.

When misbehavior is the presenting complaint about a particular child, the clinician must evaluate whether the behavioral expectations of the adults are age appropriate and within the capacity of this child's ego. The clinician also pays attention to the meaning of the behavior in the context of the child's anxieties and conflicts over drive derivatives. When thought and behavior conform to the internalized standards of the developing ego ideal, the child shows pleasure in performance of daily tasks, self-esteem, happiness, or contentment. The child displays signs of humiliation, shame or guilt, and low self-esteem when thought and behavior disappoint the strictures of internalized standards of superego. The child fears losing the love of the adults the child depends upon. Children frequently externalize blame as a defense against painful affects when a sense of being bad is unbearable. Unfortunately, when the child lies or blames others, adults may assume that the child does not know he was naughty, whereas it may be that the child does know but cannot tolerate the knowing. Children frequently express their guilt through actions in which their behavior brings about a punishment. For example, a child struggling with urges to injure a new sibling may become accident-prone.

OBJECT RELATIONS AND ATTACHMENT THEORY

Object relations theory grew out of Freud's emphasis on early experience in relationships as a source of both psychopathology and transference. The interest this stimulated in the earliest relationships of the human infant and the observational studies of young children that it spawned (35–37) have reaped extensive benefit for our understanding of the mental health needs of children. Although loosely anchored

in the tripartite model of the mind, psychoanalytic object relations theories as defined by Kernberg are "those that place the internalization, structuralization, and clinical reactivation (in the transference and countertransference) of the earliest dyadic object relations at the center of their motivational (genetic and developmental), structural, and clinical formulations" (38).

Whereas Anna Freud and ego psychologists focused more on intrapsychic conflict, object relations theorists shifted their focus to internalized dyads and interpersonal relationships. Whereas the ego psychologists focused on the child's adjustment to the triadic relationships of the oedipal phase, object relations theorists focused on the dyadic preoedipal experiences.

Object relations theorists use a metapsychology organized around the concept of an *internal representational world*, which is gradually constructed in the course of development (39). It is useful to make a distinction between object representations and images. An object representation is an enduring schema constructed from a multitude of images, each derived from a multitude of experiential impressions. Sandler (39) gives the example of a child who experiences many images of his or her mother—mother feeding, mother talking, mother dressing the child, and so on—out of which gradually is created the mother representation encompassing the entire range of mother images, all bearing the label "mother." A *self-representation* is similarly formed from the accumulation of experiences of one's own subjectivity.

Identification is the coalescence of a *self-representation* with an *object representation*. En route to a stable identification are temporary identifications and imitations with transitory changes in self-image. The object representation used as a model in identification may be based to a degree on fantasy rather than wholly on real attributes of the person from whom it derived. Identification, with its duplication of the object representation within the self-representation, is seen as a step in the loosening of the dependency tie to the object.

Object relations theory looks closely at the child's development of the cognitive awareness that a person, such as the parent, still exists even when not present. This awareness is termed object permanence. With *object permanence* the child gains greater tolerance of absence of the caregiver. A second stage of object development is *object constancy*, a term coined by Margaret Mahler (40), the capacity to maintain love for the object in the face of disappointment and anger. Following this developmental line, psychoanalytic observations reveal how fear of the loss of the caretaker generates a need for defensive maneuvers. With development the fear shifts from fear of loss of the object itself to fear of loss of the object's love and with further development to fear of loss of body integrity, often referred to as castration anxiety. Finally, as superego functions and ego ideals develop fear of loss of love generates unpleasant affects of shame, guilt, and remorse to stimulate restraint.

Attachment research has further informed object relations theory and therapeutic practice. Bowlby surmised that infants were born with a drive toward forming a

relationship with the caregiver, an attachment that was not only to gain food and love but also to be protected from danger, to gain security. Ainsworth developed methods, particularly the Strange Situation Interview, to measure and categorize the attachments of young children. Secure attachment to a primary caregiver was seen to positively affect psychological development and resilience whereas disorganized attachments were a risk factor for psychopathology. Mary Main's efforts to measure attachment experience in adults, through the Adult Attachment Interview, has led the way for a life span understanding of the impact of early object relations and of intergenerational transmission of mental health and illness.

The object relations school stimulated the development of dyadic therapies where the caregiver and child are both in the session and their relationship is the focus of the treatment.

SELF-PSYCHOLOGY

Self-psychology grew out of the work of Heinz Kohut, who found that classical transference interpretations were counterproductive when treating adults with maladaptive narcissistic tendencies. He developed an approach of sustained empathic immersion in the patient's subjective reality (41). Moving away from the tripartite model of ego psychology and the focus on internalized objects of object relations theory, Kohut considered the development of the self as a core element of mental well-being. The self, a subjective sense of "I", is in self-psychology "a predominantly unconscious structure at the core of the personality" (32). A healthy self has cohesion, continuity over time, initiative and agency, and self-esteem. Kohut recognized the importance of normal narcissism in children. Kohut theorized that children require a caregiver who reflects and affirms a child's subjective experiences of accomplishment and agency in the world. This experience manifests in therapy as a *mirroring transference*, while identifying with the caregiver as a "powerful other" whom the child can look up to and bond with manifests as an *idealizing transference*. The need for human connection and sense of togetherness manifests in a *twinship transference*. Miller (42), applying Kohut's self-psychology to children, proposes three primary drives: the drive toward internal integration, the will to do, and the need for others. Kohut postulated that children eventually learn from the realities of relationships to be flexible in their expectations of themselves and their parents and to navigate normal disappointments of daily experience. Ideally, the child learns to tolerate these frustrations, soothes the self, and builds internal structure and resilience, a process which Kohut termed *transmuting internalization*. But a range of conditions in the caregiver, the child or the environment may derail this development. Self-psychology differs from classical psychoanalysis in that Kohut found interpretation of these transferences to be unhelpful, even counterproductive, if the patient felt demoralized or defeated.

Kohut's process allows for transferences to flourish. After allowing the transference to deepen, the patients will develop a more cohesive, resilient self through tolerance of normal daily frustration with the analyst and internalization of the analyst's strength. "The child who is swooping around the living room in his cape needs to have his exuberance enjoyed, not have his fantasies interpreted as grandiose" (41).

MENTALIZATION-BASED TREATMENT

Mentalization is defined as the capacity to understand the behavior of others and one's own behavior as an expression of mental states such as beliefs, memories, and emotions. Reflective function is the operationalization of this ability to recognize mental states in oneself and others. Mentalization as a focus of psychodynamic therapy developed in the 1990s through the work of Fonagy and colleagues (43–45) who brought together ego psychology, attachment theory, and developmental research on children's emerging theory of mind. The developmental researchers demonstrated that mentalization was required for children to have the capacity to take the perspective of another, to distinguish fantasy from reality and to participate in fantasy play. Fonagy and Bateman (43,44) recognized that deficits in mentalization were found in BPD and developed a dynamic treatment for BPD based on improving mentalization, empirical tests of which are promising.

Child analysts recognized that a mentalization focus with children would move away from seeking to make the patient aware of the "whys" of their difficulties and focus instead on building the child's awareness of inner states and the child's ability to speculate on the inner experience of others. This can be done through play and through the direct experiences shared with the therapist without requiring verbal interpretation (32).

Whichever conceptual framework is utilized, dynamic psychotherapy sees the individual's motivations, impulses, and desires as important determinants of subjective experience, mental functioning, and behavior.

CLINICAL APPROACH

The clinical application of psychodynamic theory to the treatment of children and adolescents is broad, and can be combined with other treatment modalities. Individual psychodynamic therapy, based largely on psychoanalysis but drawing as well on American client-centered therapy and the child guidance model, can be used to demonstrate the fundamental techniques and practices of dynamic psychotherapy.

The line between psychoanalysis and psychodynamic psychotherapy is not distinct but in the United States rests primarily on whether the therapist trained as a psychoanalyst and on the frequency of sessions, with psychoanalytic cases requiring

at least four sessions per week, whereas psychodynamic psychotherapy tends to be once or twice per week. In terms of technique, psychodynamic psychotherapy has been more focused on facilitating the child's adaptation to their environment and improving functioning, while psychoanalysis focused more on the transference as a tool to alter the child's internal psychic structure. This distinction has been somewhat eroded, as the current emphasis on psychodynamic psychotherapy has shifted from interpretation and unconscious conflict to placing more value on intrapsychic growth in the hear-and-now relationship with the therapist.

Indications and Goals

The indications for psychodynamic psychotherapy are not diagnosis specific (22). The recommendation for individual psychodynamic therapy derives from the formulation of the intrapsychic component of the child or adolescent's condition within a developmentally attuned biopsychosocial model of dysfunction. Formulation goes beyond the simple descriptive categories of diagnosis to include life events related to the emergence of psychopathology, the pathophysiology of symptoms and problematic behaviors, and the developmental status, leading conflicts, and defense mechanisms of the child (29,46,47). Individual psychodynamic therapy is most clearly indicated in cases where the patient's difficulties are the product of intrapsychic conflict and adherence to defensive solutions or object representations that are developmentally regressive. Frequently, a child's difficult behaviors are externalizations of intrapsychic conflict. Psychodynamic therapy is indicated in cases where the etiologic factors in the social environment have resolved but the child's defenses have become fixed. In contrast, when the patient's difficulties lie in the environment or the child's own constitution, such as blindness or multiple learning disabilities, intensive individual work may be important but is unlikely to bring the youth to health without environmental interventions such as appropriate school placement.

Intensive, individual psychodynamic therapy is contraindicated in cases of severe constitutional deficits such as severe autism spectrum disorder or moderate-to-severe intellectual disability, particularly to the degree that these disorders affect capacity for self-observation and receptive language function. Intensive treatment is contraindicated when circumstances within the family or the treatment facility cannot sustain the continuity and integrity of the therapy, especially if disruption of the therapy repeats previous traumas of abandonment and unpredictability for the child.

The goals of therapy extend beyond symptom relief. A primary goal is to restore psychological development to a normal path of management of anxiety, enhanced affect regulation, improved self-esteem and frustration tolerance, age-appropriate autonomy, greater capacity for pleasure and satisfaction in school work and play, and healthy relationships with peers. Additional goals are to enhance the child's

resilience and decrease the likelihood of relapse by developing the child's capacity for understanding his or her own feelings, thoughts, and the connection between feelings and behavior. The child or adolescent comes to a more sophisticated understanding of other people's thoughts, feelings, and behaviors by learning to know and observe his own mental functions. This contributes to improved interpersonal relationships.

Opening Phase

The challenge and gratification provided by the practice of psychodynamic therapy stems in part from the requirement that the practitioner pursue diagnostic and therapeutic goals simultaneously. Thus, the psychodynamic child and adolescent psychiatrist seeks to establish a psychodynamic treatment stance from the very first contact with the adult caregiver and patient. The clinician acts in a manner that respects the parental functions of the caregiver as well as the developmentally appropriate autonomy and inner experience of the child.

The First Visit

With adolescents, particularly older adolescents, the clinician may meet with the patient for one or several sessions before meeting with the parents. This allows the adolescent to explore issues of trust with the clinician and demonstrates that the clinician's primary relationship is to the adolescent. For younger children, it is typical for the parents to meet with the psychiatrist to provide background data and to establish their own trust and confidence in the psychiatrist so that they can assure the child of the appropriateness of this undertaking. It is important to explore with parents how they will prepare the child for the first visit. If the child has expressed distress over a particular symptom, the parent may explain that the doctor is there to help with that symptom. In language appropriate to the child's age, the parents ought to tell the child that the doctor is someone who helps children with their feelings and worries by talking and playing with them.

Structuring the Psychodynamic Therapy for the Child or Adolescent

The intention in individual therapy is for the therapist and child to work together separately from the parents. The child may have difficulty leaving the parent, either because for a preschooler this is within the range of age-appropriate behavior or for an older child because of underlying conflicts. Such separation difficulties require an adaptation of technique and preliminary work with the child and parent to understand and work through the issue. The idea behind working with the child without the

parent in the room is to create a zone of confidentiality and psychic safety within which the child and therapist can explore feelings, thoughts, and behaviors. If the parent is present, the child's spontaneity is affected by the possible reaction from the parent. When the child is seen alone, the therapist is in a better position to see how the child has internalized the authority of the parents.

The psychiatrist should clarify to both the parents and the child that, although he or she meets with the child's parents on a regular basis, the confidentiality in this therapy is a "one-way street" which allows the psychiatrist to tell the child what the parents have said but precludes the psychiatrist reporting to the parents what the child has said or done. Children, particularly at the beginning of therapy, frequently will not report to the therapist current events that provide a context for understanding the child's talk and play within the session because children are very oriented in the present moment and are defensive against the affect the reporting might stir up. A meeting or phone call from the parents is important if the therapist is to know about these events. The "one-way street" implies that the therapist will share these communications from the parents with the child as clinically indicated. The child's understanding of the purpose of the therapist's meetings with parents develops as the therapy continues. It is the therapist's task through word and deed to help the child understand that, although the therapist tries to help the parents understand their role as parents of a child of this age and with these problems, the therapist cannot control the parents and will not take sides in a specific struggle between the child and parents. On the other hand, particularly with older children and adolescents, it can be pointed out that the parent has a responsibility to the child for assuring that the therapist is doing a responsible job and thus needs some report from the therapist on the progress of the work.

There are several other elements the psychodynamic therapist uses to create a special person, place, and time for dealing with feelings and worries in addition to creating a zone of confidentiality. The therapist deals with the child in a nonjudgmental and nondirective manner such as that described by Virginia Axline (18) in her classic text, *Play Therapy*. In intensive individual psychodynamic therapy, the therapist strives to relate to the child in the style McConville (48) has described as the "empathic participant" who approaches the child with the wish to know "what's it like to be you." The therapist and child explore together rather than doing something *to* or *for* the child. Eventually the therapist is *with* the child as the child examines and explores his own thoughts, feelings, and conflicts. If doctor–patient relationships are conceived of as either prescriptive, collaborative, or facilitative, the psychodynamic therapist eschews the prescriptive, choosing to be collaborative and facilitative.

The office must be suitably sturdy and equipped in a manner age-appropriate to the patients who will be treated. A separate playroom is advantageous when working with young children who are struggling to control intensely messy or aggressive

impulses. Children's activities in a play therapy tend to fall into the following categories: games with rules, physical activities, creative projects, solo imaginary play, and imaginary play with the therapist as a participant. It is helpful to have age-appropriate toys and games readily available in the office. A family grouping of animals or small dolls is useful.

The issue of limit setting will arise no matter how appropriately the office or playroom is outfitted. Common-sense limitations are necessary to protect the room, therapist, and child from physical damage. One way to understand the limits is to say, "When we are done I have to be able to clean up and have you, me, and the office/playroom back the way it was." This creates in the child's world of expression through action the same safety from real-world consequences the adult analyzes and on the couch enjoys when expressing himself or herself verbally. Frequently, the therapist is able to address the impulse toward an unacceptable action while redirecting its aim. Thus one might say, "You may not cut my dress when you feel like attacking but you may cut this paper I will hold. I can see you feel strong and safe when you are doing the cutting. You let me feel how scary it is to have someone attacking." If the child cannot be redirected, the therapist tries to prevent the dangerous action without creating a physical struggle. It is important that the therapist not become angry, blaming, or punitive while commenting on the child's struggle over the destructive wish. The therapist may comment on being maneuvered into the role of the "policeman who must keep us and the office safe." It is also appropriate for the therapist to remind the child that "We must try to find words for these feelings so you can tell me about it without things getting broken." The implementation of a set starting and ending time is the most frequently imposed limitation, as Axline (18) points out. The therapist's adherence to routine in keeping the time and dates of appointments on a predictable schedule is a necessary part of creating reliability and boundaries in the therapeutic relationship. The child's reaction to waiting in the waiting room for the appointed starting time and dealing with leaving the therapist at the end of the session can serve to reveal the particular child's conflicts and defenses.

The Interpretive Session: Structuring the Therapy for the Parents

It is important that the therapist and parents meet in an interpretive session or two to review the formulation of the child's diagnosis and prognosis in dynamic and developmental terms, and to discuss the recommendation for treatment and make the necessary arrangements. Parents understand that frequency of practice enhances the outcome when trying to learn a foreign language or master a musical instrument. In psychodynamic therapy, the child undertakes learning a new "psychological language" and developing new skills to master feelings and impulses. The patient

must be helped to counteract the resistance to change that is a natural mechanism for maintaining stability. When possible, twice per week sessions are desirable but clinicians find once per week can also be effective. Less than that may make it difficult to establish the relationship and continuity needed for successful treatment.

The wise therapist is cautious in predicting the duration of treatment unless a specifically time-limited brief treatment technique is being undertaken (22). Much depends on the stability of the environment and degree of current destabilizing stresses. What are the burdens and constraints on the parents in terms of effort and expense that might limit the duration of treatment? Parents should be told that intensive individual psychodynamic therapy is generally measured in months to a year or two. The therapist can work with the parents from the start to generate termination criteria focused on the resumption of progressive development, renewed pleasure in the child's own functioning and in the relationship with the parents (27).

The frequency and purpose of parent sessions also must be discussed. The parents and therapist need to meet to maintain an alliance and avoid undermining splits and competition for the child. Helping parents to make necessary changes in parenting techniques facilitates recovery of a healthy developmental trajectory. Frequently the therapist will need to use his or her dynamic understanding to comprehend the parents' difficulties and conflicts that interfere with their parenting (49).

Beginning the Process of Interpretation

Interpretation is the process whereby the therapist, by expressing in words what he or she has come to understand about the patient's mental life, helps the patient to observe and understand his or her inner life in a new and more complete way (20). The therapist engages the child or adolescent in the act of observation by making *attention statements* (50), comments that draw the patient's conscious attention to the content of his actions or verbalizations. Beginning with nonthreatening content, the therapist provides verbal commentary on the child's play, or enactments within the play, to reflect the child's defenses, judgments, wishes, or anxieties. As the therapeutic alliance develops, the therapist begins to draw the patient's attention to coincidences, paradoxes, and remarkable absences of affects, topics, or persons who ought to be central to the child's experience.

Middle Phase

Whereas the opening and termination phases of therapy may last several weeks to months, the middle phase of treatment lasts months to years. Intrapsychic structure is created or remodeled, new defenses are developed, and old patterns of response are relinquished during the middle phase.

The Child in the Middle Phase

The middle phase begins when the patient has taken in the structure of the treatment: the therapist's nonjudgmental attitude, regularity of appointment times, and maintenance of confidentiality. The patient implicitly knows that a goal of the treatment is to understand the way she or he feels and behaves, that everything she or he says or does can be considered in the therapy. The child's play or the older child's conversation and behavior are part of the associative process revealing the patient's intrapsychic state. The transition in late childhood and early adolescence from playing in therapy to sitting and talking reflects a developmental move from expression through action to enhanced verbal communication. Often in this transitional stage, the patient will fiddle with objects in the office; draw or play cards; or bring in homework, magazines, or a pocket full of gadgets to allow an action outlet that is non-threatening in its pullback toward child's play. In this period, the therapist needs to allow the patient to establish a comfortable blend of action and verbal expression while being alert for the ways in which either might be used as a resistance.

Resistance is an inevitable aspect of a psychodynamic therapeutic process. Lewis and Blotcky (51) describe three categories of resistance: active, passive, and compliant. The actively resistant patient expresses overt objections to the treatment, such as opposition to coming to appointments and complaints about interference in his or her life. The passively resistant youth may be stubbornly silent, withholding, and plead boredom. The compliant patient is described as eager to do the right things, to give lip service but without emotional engagement. These may be thought of as "macroresistances," appearing as an overarching response to treatment. One also finds "microresistances," moment-to-moment rejections of the therapist's offered interpretations. The child may demonstrate these by shutting down, a sudden shift of focus or behavior, or an eruption of disinhibited behavior. By observing these microresistances, the therapist can measure the intensity of the superego in opposing awareness of the mental contents the therapist was seeking to bring to the patient's conscious awareness or the weakness of the ego when it loses control of the drive.

The patient continues to develop a relationship with the therapist during this middle phase. A true transference occurs when the patient experiences in the current relationship with the therapist fixated conflicts, superego projections, and object representations that stem from previous experiences with the parents. The transference is affected and modified by the developmental achievements or delays of the patient. The child patient differs from the adult patient because the child is still living with the parents, who continue to exert influence over the patient. The patient may make a simple, current displacement of the parents onto the therapist rather than a deep transference to the therapist. In addition to the emerging transference, the quality of the real relationship with the therapist is important. The child is not the

social equal of the therapist because the child is still a child relating to the therapist as a child to an adult (52). The youth's experience with an adult who respects the child or adolescent's inner life and demonstrates an approach to understanding and managing that inner life contributes significantly to the therapeutic outcome of individual psychodynamic therapy.

It is important not to underestimate the contribution to the therapeutic process of the child's play and verbal self-expression. The play and verbalizations, by expressing heretofore-unconscious mental contents in conscious communications of speech and action, make meaning and offer an opportunity for active mastery of components of the patient's problems apart from the effect of the specific interventions of the therapist (53).

The Therapist's Mental Process

The gap between the therapist's theoretical understanding of the moment-to-moment content of the therapy sessions and what it is possible to do or say at the developmental level of the child is more evident in child psychotherapy than in work with adults. Lewis describes the multistep process by which the therapist, while keeping up the play with the child, takes "mental distance," places the immediate observations into an ongoing formulation, develops an interpretation, brings the interpretation back, and presents it to the child in the context of the play or conversation (52). For many years, interpretation was seen as the *sine qua non* of psychodynamic treatment. Recently, attention has been given to ways in which the therapist may offer developmental help or assistance rather than an interpretation (54). The choice of interpretation versus developmental assistance will be made on the basis of the formulation, particularly the assessment of ego development as age appropriate or lagging in development.

The therapist's interest is neither limited to nor primarily focused on the factual content of the patient's productions in the session. Even when a patient in late childhood or adolescence presents a narrative of an external event, the therapist listens for the defensive regulation of affect and drive in the narrative as well as the accuracy or potential distortions in the presentation of relationships. The therapist also assesses the patient's ability or inability to see multiple sides of the story. Referencing earlier material, the therapist considers what patterns emerge. The therapist may begin to formulate a reconstruction by thinking about how these patterns reflect a repetition of defenses and attitudes fixated by past trauma. The psychodynamic therapist continually monitors the patient's utilization of the therapist. Is the transference being manifested or is the patient turning passive into active and letting the therapist know what it feels like to be on the receiving end? Non-narrative material is as useful in psychodynamic therapy as is narrative. In non-narrative play, the therapist observes where shifts and disruptions in the play occur in response

either to frustration or the emergence of strong emotions or thoughts the child finds unacceptable.

The Therapist's Interventions

The basic process of constructing interpretations was laid out by Loewenstein (55) and is explored comprehensively by Lewis in "The therapeutic relationship and the technique of interpretation: The use of play in psychodynamic therapy" (52). Interpretations may be classified as *clarifications, defense interpretations, and reconstructions*. *Clarifications* bring the patient's attention to bear on his or her characteristic patterns of action and interaction but do not imply a reason for the pattern. A *defense interpretation* picks up on the drive derivative (e.g., rivalry as an aggressive drive derivative) and points out that a defense has been instituted. The drive derivative has been changed in a way that makes it manageable and acceptable to the superego (rivalry becomes the avoidance of competition). The therapist should address the defense before addressing the drive derivative when making a defense interpretation (8). The defense is acceptable to the patient. It is ego-syntonic. Drawing the patient's attention to the defense reminds the patient that he or she has a way to manage the affect or drive derivative. The patient will be more likely to tolerate looking back at the intolerable drive or affect from this position of strength.

A *reconstruction* is an interpretation that explains current feelings, thoughts, and behaviors in terms of critical past events in the patient's life or fantasies from an earlier stage of development. Reconstructions are only offered late in the therapy process. The clinical decision to offer a reconstruction to a child or adolescent requires weighing the patient's capacity to use it to "make sense" of perplexing feelings and behaviors (56). A reconstruction can be helpful to a child when it clarifies an essentially correct perception by the child at the time of the trauma that has subsequently undergone distortion (52). The therapist must consider whether a reconstruction is premature. A child too close to the trauma will reject the reconstruction in order to defend against the affects and drives the reference stirs. A reconstruction may be intellectualized or rejected because it arouses unmanageable shame or guilt.

Developmental help or assistance is a technique of psychodynamic psychotherapy with children and adolescents that has been used for decades but is only being written about and defined recently. Developmental assistance may be seen as a precursor needed to build ego capacities that will eventually allow the patient to use the play process and interpretation to gain self-understanding. Yanof (54) describes working with 7-year-old Robert, who lacked perseverance and frustration tolerance leading to poor performance in school where he had difficulty learning to read. Through much of the treatment he could use imaginative play to express his feelings of anger and unlovableness. As the summer break in treatment approached Robert

had undertaken to build Lego models:

> Whenever Robert came to something difficult, he began to complain that he could not do it—that he was not smart enough to do it. He immediately demanded that I do it for him. I made a technical decision not to do it for him but to support his plan to build the object. I did not interpret conflict, but I told him that learning how to do things was hard work and it made everyone feel like giving up. At times I gave him strategies. Much of the time he was angry at me for not doing enough. However, when he finally finished the project, he was elated (54).

Yanof was aware that Robert was lagging behind in his ability to join in his peers' pursuits and function competently. She used her skills to help him increase his frustration tolerance and experience a new competence.

The psychodynamic therapist must select the optimal context in addition to the level of interpretation. In play therapy, the therapist decides whether to work within the play utilizing the defensive protection displacement affords or to comment more directly to the child (53). The relationship between the child and therapist is a context for interpreting transference or externalization, clarifying the real, nontransference, relationship, and offering developmental assistance. Working in the play or in the patient–therapist relationship focuses the work on events inside the treatment setting, but the focus could be extended to events outside the treatment setting. The patient and therapist can discuss issues or experiences with family, peers, or school. Finally, the temporal focus may be on the past, present, or future.

Work with Parents in the Middle Phase

Success of an individual psychodynamic therapy with a child or adolescent often rests on the therapist's skill in the collateral work with the parents. The therapist must come to understand the parents' fantasies and fears about therapy, their child, and themselves as parents. Parents may come with the attitude that the therapist will redeem them from past transgressions that have affected the child, or hope that the therapist will rescue the child. Alternatively, parents may see the therapist as a rival for the child's affection or as an authority figure seeking to find fault or blame the parent. Even with the most dysfunctional parent, the therapist seeks to ally with the parent's wish to be a good parent and supports the parent in those efforts. Many parents find referral for their own individual treatment beneficial. Where there is marital conflict the therapist tactfully explores its role in the child's difficulties. If marital therapy is indicated the parents should be referred to an appropriate clinician in order to maximize the parents' effectiveness in their parenting role, minimize the possibility that the marital conflict will disrupt the child's treatment, and protect the therapist's primary relationship with the child.

In “Problems of termination in child analysis,” Anna Freud (57) lists parental reasons for terminating treatment sooner than the Hampstead Child-Therapy Clinic recommended. Parents may be satisfied when presenting symptoms have resolved but the therapist is aware that the underlying pathologic conflicts are not stabilized. Or the parents cannot tolerate transitory oppositional behaviors of the child whose therapeutic developmental gains lead to a newly achieved autonomy.

Parent work in the middle phase has the tasks of (a) facilitating the flow of information from the parents about the child; (b) counseling and educating parents both about sensitive issues in parenting and the particular child’s diagnosis, strengths, and vulnerabilities; and (c) assisting parents in advocating for the child and in case management (58).

The therapist must always plan interventions with parents in the context of what the therapist knows of the parents’ own issues and needs. Suggestions must be given with cautious awareness that parents may resist giving up a parenting behavior or pattern of relationship with the child either because it is gratifying for the parent or represents a parental defense against negative or aggressive impulses. If such resistances are present or the parent’s own conflicts can be shown to destabilize the child’s progress in the therapy, the therapist has the additional task of skillfully counseling and educating the parent (27) or assisting the parent to undertake therapy for herself or himself.

In line with more recent innovations in attachment theory and mentalization, Novick and Novick (49) have developed a novel and acclaimed psychoanalytic framework for working with parents. They list the tasks and challenges for parents across different developmental stages, the parents’ conflicts around those tasks, and the defenses that are used in managing those conflicts, which the therapist addresses with defense analysis, interpretation, and the use of transference. This allows the parents to work through what is interfering with aspects of their psychological parenting. Each phase of treatment presents parents with new tasks, the accomplishment of which consolidates progressive psychological development in the parents and the child. Both the child and the parents learn to internalize the therapeutic alliance in ways that foster their alliance with each other, which helps the parents view the child through a developmental lens (59).

Closing Phase

The closing phase presents two distinct tasks: the decision to conclude the treatment and the *termination process* by which the treatment is ended. The psychiatrist’s ability to maintain the working alliance with the patient and parents consolidates the patient’s therapeutic gains and enables the patient or family to seek help in the future if needed.

The Decision to Stop Treatment

Because intensive psychodynamic therapy with children and adolescents is a three-way contract (60) between therapist, child, and parents, the conclusion may be initiated by any one, two, or all three of the parties. The optimal termination situation is for all three to concur that the goals of treatment have been met. Premature terminations occur when there is a decision to end the therapy before the treatment goals have been met. There are two types of premature termination: disruption and interruption. Disruption refers to the decision to end the treatment because of external factors affecting any of the three parties. For example, the family may be moving or the therapist may be leaving the treatment facility. Interruption refers to a unilateral decision by one of the parties to end the treatment based on intrapsychic factors such as parents' unexamined intrapsychic conflicts aroused by the therapy. In all terminations, and particularly in the case of premature terminations, the therapist must be alert to the patient's fantasies about the reasons for ending the treatment so that they can be worked on during the termination process.

In initiating the termination process, the therapist considers the patient's ability to maintain the gains of treatment and grow in the family despite parental difficulties, the extent to which "developmental forces have been set free again and are ready to take over," (57) and the progress the patient has made in internal consolidation of intrapsychic changes. The process of consolidation of intrapsychic changes is called *working-through* (52,61). Psychoanalysis strives for a therapeutic process based on self-observation, self-awareness, and insight. Insight, according to Anna Freud, "does not occur without a working-through process," defined as the elaboration and extension into different contexts and directions of relevant interpretations. The tracing of anxieties resulting from the child's infantile perception of the world and correction of distortions of perception that were caused by the immaturity of the child's cognitive apparatus are included in her concept of working-through (26).

The Termination Process

All psychotherapies have a termination phase regardless of theoretical orientation (51). Psychoanalysts give particular attention to this phase of treatment. The understanding gained of the meaning and psychological challenges to the patient inherent in "saying goodbye" are useful to the clinician in managing the conclusion of any doctor–patient relationship.

At the theoretical level, termination is conceptualized as an experience of separation and loss. The patient, parents, and therapist bring their own characteristic approaches to separation and loss to the process. Although the therapist's attention is primarily on the patient, countertransference reactions may be triggered by the loss of the patient as a real-life object. It is essential to evaluate and address the parents'

needs in the face of the impending loss of the therapist as an ally.

The intrapsychic tasks for the patient are the resolution of the transference relationship and relinquishing of the real relationship with the therapist. The transference reaction to termination is colored by the patient's previous experiences with separation and loss. Ego functions may regress and symptoms recur. The therapist works to help the child verbalize feelings and ideas about the impending change and work through these reactions in light of the patient's current capacities, those appropriate to the patient's developmental level, and those gained in therapy. As the patient relinquishes the real relationship with the therapist, the therapist aids the patient to internalize the therapist's functions so that the patient may carry on in developing self-understanding, particularly an ability to tolerate and examine internal conflicts and ambivalence.

The technical and practical approaches to termination are designed to promote the theoretical goals. The therapist engages the patient in *active* planning and execution of the termination seeking to avoid repetition of *passive* experiences of loss (e.g., loss of parental attention with the birth of a sibling). First, the reasons for concluding the treatment must be acknowledged and the treatment goals, child's achievements, and remaining concerns reviewed, allowing the clinician, patient, and parents to gauge the patient's reaction to the impending loss. Typical reactions of children and adolescents faced with the proposition of ending therapy are (a) fear, anger, aggression, or depression; (b) return of symptoms; (c) recapitulation of the themes of the therapy; (d) adoption of the "plan" presented; and (e) a bid not to end the therapy (51).

Next, logistics of termination are addressed. Logistics include setting the date for the last session, deciding whether to make a clean break or a gradual diminution in the frequency of sessions, and clarifying follow-up plans. General guidelines for these decisions are tailored to the needs of the particular patient.

The clinician works to avoid precipitous endings without enough time to say goodbye and work through the patient's reactions. Optimally, the patient chooses the date by working with the therapist to understand why the patient feels one date is more suitable than another. A date at a natural time of separation, such as the end of the school year or the Christmas vacation, tends to downplay the reality of the termination. This may be desirable in some circumstances but may compromise a full working-through of the termination.

Following the model of adult psychoanalysis, many clinicians assume that therapy should be continued at the established intensity until the final session and stopped with no planned follow-up or contact. Anna Freud seriously questioned this approach with children and adolescents (26). She observed that, when normal development is achieved, the child detaches himself or herself in the course of time, just as children move on from teachers and even friends. Therefore, she recommended allowing the child to reduce the frequency of visits or schedule a follow-up visit.

Classical adult psychoanalysis leaves follow-up contact up to the patient. Early follow-up is regarded as evidence of the patient's failure to resolve the transference relationship. With children and adolescents who are in psychotherapy, not analysis, one must be aware that one is working two steps removed from classical adult analysis. In conditions of significant ongoing pathology, either constitutional in the child or endemic in the family, one is well advised to establish a follow-up plan. Even in less severe cases, follow-up offers several potential benefits: reinforcement of treatment gains, assessment of any possible deterioration, maintenance of the therapist–patient relationship, as well as providing valuable communication between parents, clinicians, and teachers (51). Follow-up is also beneficial for the clinician to learn more about the effectiveness of the treatment. Whether or not the clinician initiates follow-up contact, it is important for the patient to feel free to return.

RESEARCH

It is perhaps in the area of research that psychodynamic psychotherapy with children and adolescents has made the greatest gains in the past 20 years. Child psychotherapy began with the advent of psychoanalysis and the observation of children used to clarify the developmental origins of adult psychopathology, namely with Freud's 1909 publication of the case most commonly known as "Little Hans" (4). As important as this interest in developmental origins was, the research method Freud applied to the study of mental disturbances has important shortcomings by today's standards. Born out of the 19th-century Darwinian tradition of naturalistic observation, Freud's methods permitted independent evaluators to compare their findings and accumulate a remarkable and revolutionary body of theories of mental functions and their connections to behavior and to symptoms. However, in the current era of evidence-based medicine, this discipline could not continue to ignore the need for a vibrant research community to test its clinical practices and underlying assumptions.

Moving away from the case report, the emphasis in psychodynamic research has shifted to empirical research. Yet psychodynamic research retains an emphasis that is true to its underlying theoretical base. The perception that evidence-based research supporting psychodynamic psychotherapy has lagged behind other fields has likely developed from an important core discrepancy between psychoanalytic and psychodynamic research compared to research in other psychotherapy modalities: treatment interventions are designed to assess and change psychic structure and overall well-being, not only symptoms and behaviors which are easier to tangibly measure. Additionally, the focus of treatment is frequently relational, whether in the child–parent dyad or the patient–therapist dyad. Much of psychodynamic research has been aimed at those who struggle with adversity in a psychosocial context rather than with specific diagnoses. This is in keeping with the holistic trend in

psychodynamic psychiatry that favors a biopsychosocial model over a more narrowly biomedical disease model for clinical formulations. Although in recent years the advance in short-term manualized treatments has shown improvement in specific symptom reduction, it is important to keep in mind that at its heart, psychoanalysis and psychodynamic psychotherapy cannot always be boiled down to improving symptoms of specific diagnoses.

The Case Report

The case report will likely continue to have a role in the development and dissemination of psychodynamic psychotherapy practice for the treatment of children and adolescents. This is not just because of the deep attachment of psychodynamic psychotherapists to reporting their findings in this manner, but also because it is much less expensive than mounting multisubject studies that aim to achieve statistical significance. The strengths of the case report are its ability to portray the subject in all its complexity in a manner that is compelling to clinicians and lends itself to comparison with the clinicians' own cases.

A major disadvantage of case reports is the difficulty accounting for the bias introduced by the subjectivity of the clinician's perceptions, memory, and interpretation of the clinical data. There is also the concern that the clinician's awareness of an intention to write about the case will influence how the clinical material is heard. Further distortion may be introduced by attempts to disguise the case or otherwise protect the patient's confidentiality. Increasingly, patient permission is sought for publication of case material, but this practice also constrains what the clinician is willing to write.

Evidence-Based Outcome Studies

In the 1950s and 1960s, researchers reviewing the available studies of psychotherapy questioned whether outcome was affected by treatment at all. Partially in response to this challenge, overall research methodology improved, with better specification of the therapies through manualization and clearer definition of patient characteristics. With these improvements, the data support the basic tenet that psychotherapy improves outcome. Examination of the results of four meta-analyses of youth treatment outcomes published between 1985 and 1995 concluded that "the average treated youth scored better than more than three-fourths of control group youths on outcome measures at the end of treatment" (62). However, very few of the treatments deemed psychodynamic in these studies met basic criteria for that label. Many lacked an established psychodynamic theoretical framework or trained therapists. For the very few that did truly warrant designation as psychodynamic, the effect sizes were comparable with those for cognitive–behavioral treatments (63).

The Anna Freud Centre, formerly the Hampstead Clinic, has promoted psychoanalytic research since its founding in 1940. The Hampstead Indexing Project (64) established a charting requirement that had clinicians record the clinical data along several constructs critical to psychoanalysis, producing charts unmatched for their quantity and quality of clinical information. In the early 1990s, Mary Target and Peter Fonagy conducted a retrospective chart review of 763 cases, representing 90% of the cases treated at the Centre. Although the study is limited by its retrospective design, it is unlikely ever to be matched for the size of its sample, and represents one of the earliest evidence bases for psychodynamic and psychoanalytic therapy for children and adolescents.

These studies shed some light on which children might be expected to benefit from long-term psychodynamic psychotherapies. Focusing on anxious or depressive disorders, they found 352 charts (65). Seventy-two percent of those youths treated for at least 6 months showed reliable, clinically significant improvement in adaptation. Only 24% of cases had a diagnosable disorder at termination. Children under the age of 11 were significantly more likely to be well at the end of treatment than were older children. More frequent sessions led to greater improvement, independent of the child's age or length of treatment. Intensive treatment, defined as four or five times per week psychoanalysis, was significantly more helpful for children who presented with more severe disturbance, multiple diagnoses, or pervasive impairment affecting social, emotional, or cognitive functioning. Looking at demographic factors, those who were most likely to improve had higher IQ, younger age, longer treatment, good peer relations, poor overall adjustment of mother, anxiety symptoms in the mother, and absence of history of maternal antisocial behavior.

The Anna Freud Centre retrospective chart review compared four to five times per week psychoanalysis with one to three time per week psychodynamic psychotherapy. Either intensity of treatment was undertaken with an open-ended approach to length of treatment. Children under 12 benefited more from the four to five times per week treatments than from those of lesser intensity. However, adolescents, particularly neurotic adolescents, did better with the less intense therapy. In this study, 72% of children with emotional disorders who stayed in treatment for more than 6 months showed reliable, clinically significant improvement in adaptation (66). Further study of the effects of intensity and duration of treatment is necessary if we are to apply resources in a cost-effective manner.

An important question generated by outcome studies on psychodynamic psychotherapies is whether there is a "sleeper effect." Do patients continue to improve on outcome measures months to years after the cessation of the treatment? Continued accrual of benefit is seen in studies of adults treated with psychodynamic psychotherapy (67,68), and psychodynamic psychotherapy can lead to improvements in the long-term outcome of adults with treatment-resistant depression in regards to self-reported depression scores, observer-based ratings, and measures of social

adjustment (69). Psychodynamic researchers and clinicians find in the sleeper effect support for the assumption that addressing underlying psychological processes and moving a patient to a more mature and adaptive level of function will bring lasting benefit, while removing target symptoms may bring only transitory relief. Furthermore, demonstration of continued return on the investment made in a therapy directed at deeper structures can support the cost-effectiveness of treatments that may take considerable investment in therapist training at the front end.

Reviews and Meta-Analyses

Beginning in the 21st century, the obvious need for evidence-based practices helped spur further research in operationalizing and manualizing psychodynamic therapy. As is typical for research, new studies started with adults, culminating in Jonathan Shedler's 2010 paper, 'The Efficacy of Psychodynamic Psychotherapy' in *The American Psychologist* (70). This helped pave the way for similar research in the child and adolescent population. Previously, there had been insufficient studies to perform a meta-analysis of psychodynamic psychotherapy in children and adolescents. Midgley and Kennedy, in 2011 (71), were among the first to show an increasing evidence base for psychodynamic work in children and adolescents. Their review yielded 34 studies focusing on the efficacy and effectiveness of individual child and adolescent psychodynamic psychotherapy, including 9 randomized controlled trials (RCTs) focusing on anorexia, PTSD, disruptive disorders, depression, BPD, and mixed diagnoses. Their conclusion was that although there was some evidence to support the effectiveness of psychoanalytic and psychodynamic psychotherapy in young people, the studies have been of limited scale and number. One exception was studies evaluating time-limited or short-term psychodynamic psychotherapy (STPP), particularly for depression, which had an increasing body of evidence to test increasingly precise hypotheses, likely due to the repeatability of time-limited interventions. Midgley and Kennedy's review also yielded support for the sleeper effect phenomenon, noting that a pattern of more gradual, but sustained and continued improvement was noted with children receiving psychodynamic psychotherapy compared to those receiving cognitive-behavioral therapy (CBT).

Abbass et al. (72) focused on STPP for children and adolescents in their meta-analysis published in *JAACAP*. After review and selection, 11 randomized trials or RCTs met the inclusion criteria, published between 1989 and 2010, 9 of them in 1999 or later. Three studies focused on anxiety disorders; another three focused on personality or behavior problems; one investigated mood disorders; and the remaining four studies included participants with mixed mental disorders. STPP was compared to a total of 13 comparator conditions: 7 studies compared STPP to another type of psychotherapy; 3 studies compared STPP to standard care; and 3 studies compared STPP to minimal contact or waitlist controls. The mean treatment

dose in the STPP conditions ranged from 10 to 40 sessions. STPP for children and adolescents yielded large effects overall, which was consistent over almost all outcome domains with the largest effects being for general and somatic complaints, medium to large effects for anxiety, mood, and personality/personality conditions, and only small effects for interpersonal problems. However, the diversity of conditions studied may be a better reflection of real-world outcomes, and speaks to the potentially broad utility of the approach. As previously suggested, follow-up analyses revealed a "sleeper effect," in that effects increased after termination of treatment in each outcome domain, suggesting further accrual of gains over time. This again supports the notion that changes made by psychodynamic and psychoanalytic interventions are persistent over time.

Depression and Anxiety

The work of Muratori et al. (73) uses an active treatment versus community services model to examine the short- and long-term effects of time-limited psychodynamic psychotherapy for children meeting criteria for depressive or anxiety disorders. There was no difference on the C-GAS between the experimental group and the comparison group at baseline. No group differences emerged on the CBCL in the first 6 months, whereas at 2-year follow-up only the experimental group improved significantly in all summary scales. The authors describe this continued improvement as a sleeper effect, as previously mentioned, an emerging phenomena in the study of psychodynamic psychotherapies. The authors also noted that patients who received psychodynamic psychotherapy were significantly less likely to seek further treatment than were the community-treated comparison patients. This finding suggests that savings on future treatment may offset costs over time for the psychodynamic therapy group.

Zhou et al. (74) performed a meta-analysis comparing efficacy and compatibility of various forms of psychotherapy for depression in children and adolescents. Only prospective RCTs with manualized or structured psychotherapies were included, regardless of the duration of treatment. The meta-analysis concluded that psychodynamic therapy was not significantly more effective than waitlist at reducing depressive symptoms. However, there are several limitations to this meta-analysis. Among almost 4,000 patients who participated in 50 RCTs, only 35 patients received psychodynamic therapy, and they all represented one study. Additionally, this study followed patients for 9 months of treatment, whereas all of the other studies, such was with CBT and interpersonal psychotherapy (IPT), were conducted in a range of 4 to 16 weeks.

The singular study representing psychodynamic psychotherapy included in the Zhou meta-analysis was the 2007 study by Trowell et al. (75) which compared psychodynamic psychotherapy to family therapy for depression in children ages 9 to

15. Treatment was conducted over 9 months, with 72 patients separated to either 16 to 30 50-minute individual therapy sessions, or 8 to 14 90-minute family therapy sessions. The individual psychodynamic psychotherapy was based on STPP as described by Davanloo (76). In both treatment arms, 75% of patients no longer met criteria for depression when treatment ended. However, at follow-up 6 months later, 100% of the individual therapy patients no longer met criteria for depression, compared to 80% in the family therapy group. Additionally, 11% of the family therapy group was lost to follow up, compared to zero in the individual therapy group. This data supports the aforementioned sleeper effect, suggesting that individual psychodynamic therapy continues to elicit an ongoing response even following completion of the therapy. The authors suggest that those who participated in individual therapy experienced further improvement that followed the end of the treatment, which may be more clinically relevant that treatment gains achieved in only the first 4 to 16 weeks as in the other studies.

Midgley's group, moving on from their aforementioned review of clinical trials (71), are in the process of steering a large-scale clinical trial in the United Kingdom, the Improving Mood with Psychoanalytic and Cognitive-Behavioral Therapy (IMPACT) Study (77). This study aims to be the largest clinical trial examining psychodynamic psychotherapy with children and adolescents, and is an RCT based on the authors' treatment manual for STPP for adolescents with moderate to severe depression, which is currently in press (78).

The *Manual of Panic-Focused Psychodynamic Psychotherapy* (PFPP) developed by Milrod et al. (79) at Cornell University Medical College is a 12-week, 24-session individual psychodynamic psychotherapy emphasizing unconscious thought, free association, and the centrality of transference. The hypothesis underlying PFPP is that common psychodynamic conflicts in panic disorder involve difficulties with separation and independence as well as recognition and management of anger and sexual excitement. These issues are addressed as they arise in the sessions and particularly as they arise in the transference under the pressure of impending termination. Looking separately at the results for patients 18 to 21 years of age showed that these late adolescents, or young adults, did well with PFPP (80). The research team has developed a manual for the treatment of adolescents (PFPP-A) (81). The major changes from the adult version focus on a psychodynamic approach to the work with the adolescent's family and the particular countertransference issues adolescents generate.

Child and Adolescent Anxiety Psychodynamic Psychotherapy (CAPP) is a newer, manualized, twice weekly treatment for children ages 8 to 16 with primary diagnoses of generalized anxiety disorder, social anxiety disorder, or separation anxiety disorder. Much akin to the traditional psychoanalytic process, treatment is broken down into three phases encompassing up to 24 sessions. This approach assumes that anxiety symptoms represent psychological meanings that can be identified by

exploring fantasies and feelings related to the symptoms (82).

A German group at the University of Leipzig manualized a short-term psychodynamic treatment program for 4- to 10 year olds with anxiety disorders, Psychoanalytic Child Therapy (PaCT) (83). PaCT comprises 20 to 25 weekly sessions during which therapist, parents, and child collaborate to identify and modify core conflicts underlying the child's symptoms and family dysfunction. In their pilot study of 30 children randomized to PaCT or wait list, two-thirds of the treatment group were in full remission after treatment (average 40 weeks) compared to zero in the waitlist. After the waitlist families received the treatment, the team collected follow-up data from 25 families after 6 months, 22 of which showed complete diagnostic remission.

Medical Illnesses

In the early 1990s, Moran and Fonagy (84) used success of diabetic control, as manifested in HbA1C levels and other physiologic tests, as an outcome measure for the efficacy of a brief, intensive psychoanalytic psychotherapy for adolescents with insulin-dependent diabetes. Both the treatment and control groups manifested significant psychiatric symptoms on psychological assessment. The treatment group showed considerable improvement in diabetic control on HbA1C, both at the 3-month and 1-year follow-ups, while the control group returned to pretreatment levels. The most interesting aspect of this study from the perspective of psychotherapy efficacy measurement is its use of a physiologic marker for the measurement of outcome. In this way, the investigators sidestepped debates about the relevance to psychoanalytically oriented treatments of currently available psychological measurements of change. More clinical research projects are underway aimed at addressing parental traumatic stress and strengthening mentalization capacities to increase the parents' emotional availability to their medically ill children (85).

Trauma

Like the diabetes study, the work of Trowell et al. (86) on psychodynamic psychotherapy for sexually abused girls focuses on youths struggling with a significant life stress rather than treatment for a specific psychiatric diagnosis. However, psychiatric disorder was common among the total of 81 girls who were assessed at baseline: posttraumatic stress disorder in 73%, major depression in 57%, generalized anxiety disorder in 37%, and separation anxiety disorder in 58%. Seventy-one girls, ages 6 to 14 years, who had experienced sexual abuse were enrolled as they presented for treatment at two clinics in London. Random assignment was made to the study treatment of an individual psychodynamic psychotherapy or a comparison group therapy that combined psychotherapeutic discussion of

relationships with psychoeducational topic-focused sessions. The psychotherapy consisted of weekly sessions of manualized, nondirective, psychodynamic psychotherapy. The child's or adolescent's caregiver was seen about every 2 weeks for support and guidance. Both treatment groups showed a substantial reduction in psychopathological symptoms and an improvement in functioning, but with no evident difference between individual and group therapy. However, individual therapy led to greater improvement in severity of PTSD and "persistent avoidance of stimuli" measures on the PTSD scales.

Attachment Difficulties in Mother-Infant Dyads

The dyadic treatment of mothers and their preschool children is an area in which research on psychodynamic interventions is moving forward. This research brings together the work of Bowlby, Ainsworth, and Main on the quality of attachment of infants and toddlers to their caregivers with the work of Selma Fraiberg and her collaborators on the intergenerational transmission of internal representations, aggressive conflicts, and negative self-representations (87). The work of Toth et al. (88) at the University of Rochester testing preschooler–parent psychotherapy (PPP) and of Lieberman, Van Horn, and Ippen at the University of California–San Francisco evaluating child–parent psychotherapy (CPP) are fine examples of this active area of research.

Toth et al. (88) took as their study population maltreated preschoolers and their mothers. Mothers and their preschoolers receiving PPP were seen for weekly, 60-minute, dyadic sessions with a trained therapist, usually at the treatment center but with occasional home visits. The interventions focused on the mother's reflective functioning—the mother's capacity to make sense of her child's internal experience and to understand the child's internal mental states. Increased capacity for reflective functioning allows the mother to anticipate and react appropriately to her child. By using observations and empathic comments, the therapist assists the mother in recognizing how her internal representations are enacted during her interactions with her preschooler. Although the therapist's interactions with the child may provide a model of adult–child interaction, no effort is made to be didactic or explicitly instructive. The therapist seeks to respond to maternal utterances and interactional patterns, linking current maternal conceptualizations of relationships to mothers' own experience of care in childhood.

Lieberman, Van Horn, and Ippen's CPP (89) also takes the mother–child dyad, rather than an individual child patient, as the treatment unit. As with PPP, CPP, a treatment developed for preschoolers exposed to marital violence, draws on attachment theory and the work of Fraiberg. CPP consists of weekly parent–child sessions for 1 year, during which the therapist's interventions are guided by the unfolding child–mother interactions and by the child's free play with

developmentally appropriate toys selected to encourage social interaction and to elicit trauma play. The therapist seeks to guide the mother and child in creating a joint narrative of the traumatic events they experienced. Additionally, the therapist seeks to change maladaptive behaviors and support developmentally appropriate interactions between mother and child. Children assigned to CPP improved significantly more than children receiving the community treatment. Children in the test treatment demonstrated decreased total behavioral problems and decreased traumatic stress disorder. Newer attachment-based treatment programs, such as the Mothers and Toddlers Program (a 20-week intervention for substance-abusing mothers) and the Peaceful School Project are good examples of contemporary attachment-based psychodynamic interventions helping children and families in specific clinical or environmental contexts. There is a growing evidence base to support dyadic, parent–child implementation of psychodynamic psychotherapy for a wide range of contexts (90).

Eating Disorders

Although family-based therapeutic treatments have long been the treatment of choice, and perhaps the gold standard of treating adolescents with eating disorders, there is some evidence to suggest that psychodynamic psychotherapy can be effective. In the treatment of 12 to 19 year olds with anorexia nervosa, psychodynamic psychotherapy was found to be comparable to family-based treatment after 12 to 18 months in regards to achieving target weight. An independent study comparing psychodynamic psychotherapy to family-based therapy showed that age was a significant moderator, with older patients benefiting more from individual therapy and younger patient benefiting more from family-based therapy, in both short- and long-term follow-up (91). Psychodynamically informed therapies, including family-based therapies, represent an important option for young people, although further research is needed (92).

Mentalization-Based Treatment of Adolescents (MBT-A) and Emerging Borderline Personality Disorder

As previously discussed, mentalization refers to the ability to understand human behavior as it relates to internal feeling states. Mentalization links psychodynamic and attachment theory with developmental and neuroscientific research. An inability to mentalize may be linked to disordered self-experience and incapacity to understand and relate with others in socially and emotionally meaningful ways. Neuroimaging studies have shown that the capacity to mentalize can be affected by stress and arousal in the context of attachment relationships (15). A growing body of literature suggests that disruptions in mentalizing are a core feature in adolescents'

increased susceptibility to developing affective dysregulation, impulsivity, and instability in relationships and self-image that are much akin to the clinical syndrome of BPD. Mentalizing-Based Treatment for Borderline Personality Disorder (MBT-BPD) in adults now has a substantial literature base; that for MBT-A is preliminary, but promising (15). The objective in all mentalization-based treatments is for patients and families to discover how they think and feel about themselves, others, and their relationships, how thoughts and feelings give meaning to behavior and actions, and how disruptions in this process lead to maladaptive behavior and unstable relationships. As often is the case, assisting families in this process alongside the adolescents may be crucial, as a coercive, nonmentalizing interactions in families can reinforce maladaptive behavior in these adolescents.

MBT-A has been evaluated in adolescents who meet criteria for BPD, engage in self-harm or other self-destructive behaviors. Rossouw and Fonagy (45) manualized a year-long treatment program with weekly individual and monthly family sessions aimed at enhancing mentalizing abilities; a 3- to 12-week version for inpatient and partial-hospital programs was also developed by Bleiberg and Williams (93).

Regulation-Focused Psychotherapy for Children (RFP-C) is a manualized psychodynamic approach to children with externalizing behaviors who may be considered to be in the emerging borderline personality category (94). RFP-C is derived from ego psychological approaches to psychodynamic therapy addressing the disruptive behaviors in these poorly regulated children as defenses against affect. This treatment is just beginning pilot studies but is very close to the treatments that did well for children with disruptive behavior in the Anna Freud Centre retrospective studies (95).

Trends and Future

A review by Palmer et al. (90) of RCTs shows a growing body of evidence supporting the use of psychodynamic psychotherapy implemented in family-based contexts, rather than just the more traditional individual therapy, as the family-based treatment may produce quicker results. This is particularly true with children with internalizing disorders. It is likely that family- and parent-focused psychodynamic therapies may make their way to the forefront, and perhaps it is in this mode that psychodynamic psychotherapy may be most at home in the future. Additionally, some suggest that adopting different target measures of improved outcome, such as performance on cognitive activities or physiologic indices, may yield larger effect sizes, and that psychological symptoms are not the only target of psychodynamic psychotherapy.

With technologic advances and increased focus on biomarkers for psychiatric disease and treatment, one wonders if treatment outcomes and predictors for psychodynamic psychotherapy may be discovered through genetic research or

neuroimaging. To date, several studies have shown that patients with various psychiatric disorders have improved or normalized neuroimaging findings after psychodynamic psychotherapy (96). Perhaps similar findings are over the horizon.

Furthering the evidence base is designed to inform clinicians in routine practice regarding treatments that offer the best outcomes. Therefore, despite the call for growing numbers of RCTs and meta-analyses, observational studies in the clinic may still play an important role in showing the power of psychodynamic psychotherapy. Edlund and Carlberg of Sweden (97) present results of 218 patients ages 14 to 24 seen from 2002 to 2009 at an institute providing outpatient psychodynamic psychotherapy, using ratings of global functioning from either the therapists or the patients. Improvement was seen across the board. What appears to be most likely is that researchers must follow current trends of what is considered the highest grade evidence to continue proving what is already known: the effectiveness of psychodynamic and psychoanalytic therapies for children, adolescents, and their families for a wide variety of conditions. It appears that future research, growing the body of literature showing that psychodynamic psychotherapy is an effective treatment in children and adolescents, is on the horizon if not already upon us.

CHAPTER 6.2.6 ■ GROUP THERAPY

NANCY E. MOSS, GARY R. RACUSIN, AND CORINNE MOSS-RACUSIN

INTRODUCTION

Group treatment stands as a powerful intervention available to professionals serving the child and adolescent population. The aim of this chapter is to provide an intellectually informed clinical guide to implementation of this modality of treatment. The chapter begins by placing group therapy in a historical context and considering aspects of group development. A theoretical framework for group treatment is then discussed, followed by examination of the many pragmatic issues to be managed in offering a therapeutic group. Parent involvement and leadership functions are then considered. A description follows of special applications of group treatment for HIV-affected youngsters and individuals on the autism spectrum. Indications and contraindications for group treatment, as well as training and supervision needs, are then examined. The chapter concludes with a discussion of the efficacy of group treatment and the status of research in the field.

Group treatment with children and adolescents has a long history (1–6). At the end of the 19th and beginning of the 20th century, early efforts were designed to rehabilitate particular medically affected populations (7). Group homes that included intensive attention to group process were organized to treat adolescents with severe behavior disorders (8). Heavy use was made of psychodrama in treating a variety of problems in a group context (9). Related to the settlement house movement, groups were offered to youngsters from lower socioeconomic strata to expose them to aspects of more affluent, mainstream culture (10). The hope of this last type of group was that such exposure would elevate the group members' overall functioning, improve their behavior, and facilitate their moving into productive adulthood.

As the 20th century continued, many groups for children and adolescents were offered under the auspices of child guidance centers and community mental health centers. Activity groups for children became prominent, based on the premise that participation in age-appropriate play activity would promote better mental health. Later in the 20th century, groups based on the principles of behavior modification were conducted to treat numerous psychiatric problems. As the 20th century closed and the 21st century began, social skill groups and manual-based psychoeducational groups designed to impart specific curricula assumed greater prominence (6).

Just as the broad field of group therapy with children and adolescents has developed over time, many clinicians and researchers involved in child and adolescent group therapy have formulated the developmental stages through which each individual group moves over the course of its operation (11–14). Generally, groups move through an initial phase during which the foundation is laid for group

cohesion. The group then often has a relatively euphoric period when the members have great hope and feel relief at having become part of the group. This period may then be followed by a more discouraged period as the full impact of the presenting problems becomes more evident. With good leadership, the group is then able to move into a more realistic, hardworking phase of its life. Ultimately, the group must go through the termination phase, during which members need help in internalizing and consolidating the gains made and in preparing to separate from the group.

Stages of group development take on different contours in both open-ended and shorter-term, time-limited groups. The relevance of group development to leadership interventions varies greatly depending on the type of group offered. In groups intended to be long term but with a planned ending date, correct interpretations of group behavior should rest on a sound understanding of the stage at which a group is operating. In contrast, in open-ended groups, members are admitted and discharged as dictated by their clinical needs. The group as a whole remains in a hardworking developmental stage as it incorporates new members and disengages from departing ones. Finally, in briefer, time-limited groups, group developmental stages become less relevant. The group tackles its specific tasks, knowing throughout that termination is close.

THEORETICAL UNDERPINNINGS OF GROUP THERAPY

Amid the daily pressures of clinic life and professional practice, therapeutic groups are often designed and implemented without a foundation of theoretical knowledge. Rather than being derived from comprehensive theory, many groups reflect professionals' efforts to manage time and caseload constraints. Such an atheoretical approach limits severely the range and effectiveness of group interventions. Without a theory for guidance, group leaders must rely more purely on intuition and moment-to-moment creativity in responding to the ongoing demands of group life.

Theory-based group practice allows for much more coherent intervention and thereby capitalizes most fully on the potential impact of a group treatment. A theoretical foundation allows group leaders to offer a range of group treatments that address group structure, procedures, and leadership style. When issues of structure, procedure, and essential leadership skills are mastered, they can be applied to any clinical population or specified problem. A guiding theory is also invaluable in navigating any single meeting of a group. Since each group meeting generates a wealth of clinical data and information, myriad decisions face the group leaders regarding intervention choices. A theoretical basis provides a map for leaders to discriminate among levels of information and thereby determine the most appropriate responses and interventions at any point in time.

A variety of theories have been used to guide group practice. Cognitive behavioral, psychodynamic, and gestalt theories are prominent among those that have

been mined for group practice (15). Choice of a theoretical guide should be at the discretion of the leaders. Designation of a comprehensive theory and its full utilization are much more important than which particular theory is chosen.

While many theories can be helpful in group leadership, Bion's group-as-a-whole is a powerful theory available to group leaders (16–21). Originated in Britain by Wilfred Bion and his psychiatric/psychoanalytic colleagues to assist the British military during World War II, the theory posits that group structure and strong leadership are critical variables in group practice. Essential features of this body of theory are discussed below.

Consistent with its name, this theory asserts that the group as a whole is greater than the sum of its parts. The group as a whole is the "organism" to be considered. Individuals are believed to participate in the group life as dictated by their singular needs and capacities, in interaction with shared group needs and capacities. Individual behavior is therefore always understood as conveying information not only about that individual but about issues that require the group's attention. Individual behavior displayed in a group context is always believed to be a necessary expression by the group and to have relevance for the group. To have the greatest therapeutic impact, then, interpretations of behavior and interventions should be aimed at the group level.

The theory posits further that a group must be distinguished from a more casual collection of individuals. This distinction rests on identification of the group's shared task. The fundamental task of the group becomes the bedrock on which the group's life is based. As the group proceeds, practice decisions and behavioral interpretations should always be evaluated by their fidelity to the fundamental task of the group.

There is a range of tasks that can be addressed in therapeutic groups for children and adolescents. These tasks fall in roughly five categories. Traditionally, many groups were organized to provide formal, insight-oriented, psychodynamic psychotherapy. The task of such a group is to use both talk and play, as appropriate, to help make the unconscious conscious, presumably leading to greater psychological health characterized by intentionally chosen appropriate behaviors. While such formal psychotherapeutic groups still exist, briefer and more behaviorally oriented types of group work with children are now offered more widely. This broadening of the kinds of groups offered can be understood as a response to increased financial constraints in the mental health field. A second type of group offered to children and adolescents is the social skills group. The task of this type of group is to increase the members' repertoire of age-appropriate social skills, thereby enhancing the members' interpersonal relationships overall and improving their peer relationships, in particular. The task of a third type of group, a support group, is to acknowledge a traumatic experience or set of circumstances common to all group members and to provide clinically informed support aimed at facilitating good coping skills. Some

groups are more formally didactic, taking on the task of imparting knowledge and teaching skills relevant to a particular psychoeducational problem. Finally, a fifth type of child/adolescent group is a goal-focused group. This group has the task of marshalling internal and external resources to allow the members to attain a specified, tangible goal or create a tangible product.

For groups to be effective, leaders must begin with a clear conceptualization of the group's task. Leaders must be vigilant about remaining true to the task, carrying out actions relevant to the designated task and foregoing actions that would actually be aimed at an alternate one. To take on task-irrelevant issues essentially makes an offer to the group that can't be delivered fully and thereby threatens the integrity of the leadership and the group as a whole.

Members' conceptualization of the group task operates differently than the leaders'. Members must hear a clear statement of the group's task as they enter the group. Otherwise, they would be justifiably confused about the nature of their participation and expectations for them to work would be unfair. It is often true, however, that group members develop a full understanding of the task only as they participate in the life of the group. Many times, the nature of the task is so difficult that the task itself only becomes truly understandable psychologically as the group begins to have some initial success in task accomplishment and develops greater capacity to tolerate the tension involved in group participation.

Once the group begins, its activity can be defined in two ways, rational work and/or basic assumption life. Rational work is defined as any activity that moves the group further toward accomplishment of its task. For groups of children and adolescents, it is essential to note that rational work will be expressed in developmentally determined forms. For young children, this might be a variety of play activities. For older children and adolescents, more conversation might be used. Thus, a firm grasp of normative child/adolescent development is necessary to allow group leaders to recognize and interpret accurately the members' behavior.

This body of theory presumes, however, that carrying out rational work is extremely arduous. By definition, the task of a therapeutic group is difficult. If the task were an easy one, creation of the therapeutic group and its dedication to ongoing effort would be unnecessary. Formal psychotherapy groups lead members to confront some of their most basic unmet needs and deficits. Social skill groups highlight fundamental interpersonal impairment. Support groups focus on specific traumas that engender significant distress. Didactic groups require substantial cognitive growth, typically regarding emotionally charged topics. Goal-focused groups elicit disturbing emotions about the necessity for reaching the specified goal. In addition to particular group characteristics, group membership itself is understood as a psychologically challenging transaction. Each member must relinquish enough individuality to join fully with the group as a whole. At the same time, each member must retain a firm hold on a singular identity. Balancing of these requirements requires considerable

psychological energy and strength.

When the difficulties posed by rational work become too great, groups are assumed to feel that their continued existence is threatened. To defend themselves, they retreat to basic assumption life. Basic assumption life is defined as a variety of defensive postures, each expressing a fundamentally irrational notion of how the group may avoid the perils of rational work and thereby continue to exist. It is incumbent upon the leaders to recognize basic assumption life and to interpret it appropriately. Group-as-a-whole theory states that such interpretation and exploration of the group's reaction are instructive for the group and ease the group back into a rational work mode.

Group-as-a-whole theory was developed as a compelling, comprehensive approach to group operation and leadership primarily appropriate for adults. Considerable group experience has demonstrated that, with appropriate developmental modifications, the theory is equally useful with children and adolescents (21,22). Embedded as the theory is in group and organizational life, it takes the fullest therapeutic advantage of the group treatment modality.

PRAGMATICS IN THE OPERATION OF GROUP THERAPY

Along with theoretical underpinnings, a number of pragmatic considerations have a significant impact on the usefulness of group treatment. Many of these considerations are explored by Lomonaco et al. (3), Schamess (23), Schectman (24), and Slavson and Schiffer (25). Relevant considerations are discussed below.

Recruitment of Members

The main goal of the recruitment phase of group treatment is to identify members who need to accomplish the designated task of the group and who are able to work together toward that task accomplishment. Such identification requires sufficient clinical knowledge about each prospective group member. Several concrete steps facilitate the identification and recruitment process. First, group leaders must communicate clearly and broadly with all potential referral sources in an enthusiastic and welcoming manner. Referrals should be encouraged by conveying an eagerness and willingness to be helpful to colleagues and potential group members. Once a referral has been suggested, group leaders need to determine whether the child or adolescent has been fully evaluated. If a psychiatric evaluation or psychological assessment has been completed recently, the results of the evaluation should be reviewed carefully to assess compatibility with the designated group. If no recent evaluation has been done, group leaders either need to obtain in-depth clinical information about the prospective member from a clinician with ongoing knowledge about the member, or the leaders need to carry out a relevant evaluation. An in-depth,

clinical understanding of each prospective group member is necessary to ensure appropriate group composition. Should the group leaders then determine that the prospective group member is inappropriate for the designated group, alternative treatment options or experiences should be suggested to the child or adolescent and his/her family. Should the group leaders conclude that the referral is appropriate, the leaders should meet with the group member's parents to describe the group in detail, to plan for the child's or adolescent's course in the group treatment, and to answer parent questions. The leaders should then meet with the prospective group member to again describe the group, make certain that the member appears to fit admission criteria, and to answer the child's or adolescent's questions. At times, actually meeting with the prospective group member raises particular concerns about potential group membership. These concerns should be taken up with parents and referring clinicians to allow for confident admission decisions. If all are then agreed and comfortable, a date should be set for entrance into the group.

Diagnostic Composition

The question arises often about the relative merits of diagnostic homogeneity or heterogeneity in a group. This question should be resolved in relation to the proposed task of the group. A group designed to address specific, diagnosis-related issues would clearly demand diagnostic homogeneity. Thus, for example, a psychoeducational group for children with diabetes would, by definition, require that all members have diabetes. Similarly, a support group for HIV-affected youngsters would require that all members had direct experience with HIV infection. In contrast, a group with a developmental or psychotherapeutic task would thrive on diagnostic heterogeneity. Mirroring the diversity to be encountered in naturalistic environments, such group heterogeneity would bring differences in perspective, observational capacity, and interpersonal relatedness that would allow for spirited, mutually beneficial interactions among members and leaders. To illustrate, a social skills group would do best if members all displayed impaired social functioning but did so for widely different reasons. In such a group, a socially inhibited, depressed member might be able to give very age-appropriate social feedback to an idiosyncratic member on the autism spectrum, while an impulsive, acting-out member might be able to challenge the inhibited member toward more vigorous, instrumental interaction.

One important caution should always be considered in regard to diagnostic composition of the group. To the greatest extent possible given real-life contingencies, a group should not contain only one representative of any critical attribute or category. A solitary representative of any salient classification—racial, religious, ethnic, gender, or level of diagnostic severity—invites isolation and hinders significantly the potentially useful interventions implemented by the leaders.

For example, a group for psychotic youngsters could be extremely beneficial, offering them evidence that they were not fully alone in their disorganization, and teaching them pragmatic coping strategies. Placement of a single psychotic child or adolescent into a group of more realistically functioning members, however, intensifies the psychotic member's sense of isolation, highlights his/her impairment, deprives that member of appropriate group interventions, and frightens the group as a whole. In forming a group or admitting new members to an ongoing group, then, every effort should be made to include members who share important, relevant attributes with at least one other member.

Group Size

Therapeutic groups for children and adolescents should be big enough to generate multiple, challenging interpersonal interactions and to allow for both dyadic, triadic, and whole-group activities. At the same time, the groups should be small enough to permit a sense of intimacy and close personal attention. Groups composed of 4 to 6 members are ideal for most therapeutic tasks. While not overwhelming to individuals, groups of this size can continue to work productively even with occasional absences due to member illness, vacation, or other reasons.

Gender

As with the issue of diagnostic consistency, the question of same-sex versus mixed-sex groups is often debated and should be resolved in reference to the group's task. Traditionally, therapeutic groups were offered to single-sex populations. More currently, common practice has changed. For most tasks in groups of children and adolescents, mixed-sex groups prove to be most useful, since interacting with others of both sexes again parallels most closely real-life experience. Group members derive benefits directly applicable to the demands and challenges of daily life. There are, however, some groups that should remain single-sex groups. These are the groups designed to address sensitive issues related to sexuality, aggression, and/or sexual abuse. The need for comfort, trust, and empathy in such groups is difficult enough to satisfy but would be even more difficult in a mixed sex group.

Age Range

In actual clinical life, age ranges are rarely absolute. Developmental and school grade levels tend to influence and sometimes extend the age range of a group. Still, a general age range of 2 to 3 years is most appropriate. It is important, too, that the span of years be contained within one developmental phase of life. This type of clustering allows for the necessary commonality of experience and capacity to

benefit from group interventions.

Setting

A space should be dedicated to the group on a consistent, reliable basis. Two conditions are most important in identifying a group setting. First, the setting must be private for the duration of each group meeting. Intrusions by individuals not associated with the group are very destructive of the group process. Second, the setting must be furnished and equipped in a developmentally appropriate manner. While leaders should work hard to limit damage to the physical space, some wear and tear in the environment must be a realistic expectation in working with children and adolescents. It would be too difficult to carry out the work of the group if leaders were faced with constant worry about protecting a more adult-oriented room that contained objects or interior decorations of great value. If these conditions are met, groups can adapt to many different kinds of spaces of varying sizes.

Materials

When embarking on group treatment for children or adolescents, leaders are often tempted to amass a large collection of tempting, exciting, attractive play materials. In actuality, a big, tempting array is usually over stimulating to a group and leads to excessively active, disorganized interactions. A modest amount of developmentally appropriate materials facilitates much more productive group interaction. For adolescents, some decks of cards, a few advanced board games, and some limited art materials would likely be sufficient. Groups at this adolescent level tend to engage more in conversation than activity. Younger groups rely more heavily on activity as the vehicle of their clinical work. Thus, for elementary and middle schoolchildren, it would be best to provide decks of cards, a larger number of simpler board games, limited art materials, some building toys such as Legos, and something that allows the group to engage safely in an indoor large-motor activity, for example, a soft, inflatable beach ball or a plastic indoor bowling set. Preschool groups do best with a small amount of building toys, some drawing materials, a few very simple board and card games, and materials that promote fantasy play such as a dollhouse or dress-ups. Whatever the age of the group, it would always be best to do with fewer rather than more materials.

Food

In carrying out group treatment with children and adolescents, the challenge of group participation should always be remembered. Management of the self in relation to the group as a whole is daunting, in addition to the difficulty of the actual therapeutic

work. In recognition of the challenges faced by group members, it is helpful to provide a snack as a tangible support to the group. In addition to its nurturing aspects, time spent eating together as a group promotes more intimate, relaxed interactions that often help with task accomplishment. The logistics of providing food in the group are important, as well. The exact food and accompanying drink to be provided should be very simple and should be decided by the group leaders. Accommodations should be made to any specific dietary requirements of group members. The group should be told that a set amount of snack will be offered to each member. Group protest should be expected no matter what the designated amount of snack is. Such protest should be understood as part of the group establishing and maintaining its trust in the group leadership. Leaders should adhere to the snack plans set forth at the outset of the group. The only useful exceptions to these snack plans involve either essential dietary restrictions on the part of individual members or special occasions. In regard to dietary restrictions, parental report sometimes indicates that a child cannot tolerate a food or drink for medical reasons. At other times, religious or cultural beliefs dictate acceptable versus unacceptable food. These specific needs should be accommodated by the entire group, whenever possible. If group-as-a-whole accommodations are impractical or impossible, the individual member should be cared for appropriately with a simple explanation offered to the group. In regard to special occasions, from time to time the group may observe a holiday if such observance is consistent with the task of the group. On these occasions, it is helpful to have the group plan together about food and drink, with the leaders retaining veto powers if the plans get too lavish to be practical.

Duration

Length of each meeting and lifespan of the group should both be considered. Regarding meeting length, 1 to 1½ hours is an optimal amount of time for a group meeting. Less than 1 hour deprives the group of sufficient time to enter fully into work on its task. Instead of concentrating on the work, both leaders and members feel the constant pressure of time and spend most of their energy hurrying to finish. More than 1½ hours is simply too exhausting. Many groups meet for 1¼ hours and find that duration to be very comfortable. In public school settings, the demands of the school day often dictate that groups must meet for only 20 minutes to ½ hour. Under such conditions, leaders should work hard to design group agendas that can be implemented realistically. Regarding group lifespan, professional preference and practical realities of organizational life in many settings lead to decisions to offer time-limited groups. In such settings, constraints on professional availability, organizational resources, theoretical outlook, and regulations of third-party payers may all require a time-limited group. In other settings and under different conditions, long-term, open-ended groups are still offered, as they were more routinely in earlier

years. It should be understood that time-limited versus long-term groups offer different possibilities for meaningful work and can accomplish different tasks. Time-limited groups are best for teaching specific, discrete skills, or imparting well-specified information. They can also be very useful for individuals who could not tolerate the intensity of long-term interpersonal interaction. Brief groups may also lend themselves more readily to empirical research designs. In contrast, long-term, open-ended groups are best for facilitating more fundamental, broader changes in designated areas of personal functioning. To carry out formal, intensive psychotherapy in a group format, to engender genuine change in naturalistic social functioning, to provide support with some life-threatening situations, there is no substitute for a long-term, open-ended group experience.

MEETING PROTOCOL MODEL

To allow the group members to rely fully on the structure of the group, group meetings should always follow the same protocol. The exact amount of time allotted to each portion of the agenda may vary based on the leaders' appraisal of the group work in any particular meeting. What should never vary is inclusion of each segment of the meeting protocol in each meeting. Omission of any segment, regardless of how justified such an omission might seem by the events of the moment, will always diminish the group's trust in its leaders and in the structure of the group and will, therefore, impede the work of the group. A useful protocol follows.

Gathering of Members

A comfortable place for the group to go to on arrival at the clinic, school, or private therapy office should be designated. It should be communicated clearly that parents or substitute caregivers retain responsibility for behavior management in the arrival area. Exactly at the time for the group to begin, the leaders should go to the arrival area to greet the members and bring them to the group meeting room. Acceptable behavioral standards and full physical safety should be maintained as the group is escorted to the meeting room. In some behaviorally challenging groups, members may need to be escorted in subgroups if moving as a whole group is too stimulating. In public schools, this gathering of members may need to be modified to include bringing the group members from their classrooms. Once in the group meeting room, members should be guided to settle into their designated places, putting away any personal belongings as directed. Overall, the purpose of this period is to welcome the group members and help them settle back into being together.

Talking Time

The group should be seated so that everyone can see each other. In most groups, a circular, square, or rectangular seating arrangement on the floor or single chairs is appropriate. In some groups for more psychologically disorganized individuals, the informality and intimacy of such an arrangement might be overwhelming. Such groups should be seated around a table for more formality and support. The first purpose of talking time is to allow the leaders to make any necessary announcements regarding member absences, upcoming events, or other practical issues. The leaders may also use this time to lead the group in discussion of a particular occurrence or ongoing situation that requires the group's consideration. The second purpose of talking time is to promote sustained, verbal interaction among the group members. Each member is encouraged to tell the group something of significance, if they choose to do so. In older, more mature groups, this part of talking time might be fairly informal. To the extent that the members can manage themselves, the leaders might be able to allow for free conversation. In younger, less mature groups, members' participation in talking time has to be managed much more carefully by the leaders. A helpful model is to have each child/adolescent talk to the group about one or two topics of importance and then turn to the next child/adolescent and elicit a question or comment about what was just related. This model teaches group members about listening to one another, staying on topic, responding to someone else, and about distinguishing between questions and comments. In psychotherapy and clinical support groups, talking time may become quite lengthy as the group moves more deeply into its work. In social skill groups, leaders should limit talking time to approximately 10 minutes to allow for sufficient opportunities to engage the group members in fuller social interaction. Leaders should always be the ones to announce when talking time is completed.

Activity Times

The group activity times are periods of the group meeting devoted to developmentally appropriate board or card games, role-playing, projects, arts and crafts, physically active indoor games, and other forms of play. These activity times are intended to enhance age-appropriate, multifaceted interpersonal interaction aimed at accomplishing the group's task. The activity periods are divided between group activity and free activity or play time. The group activity time is a period during which all the members must engage in a whole group activity. In psychotherapy groups, the groups should be free, within parameters specified by the leaders, to choose this whole group activity. The process of choosing and entering into the activity is as important to the work of the group as the activity itself. In social skill and more didactically oriented support groups, the group activities should be designed by the leaders based on adult observations of areas of need in the group. First and foremost, the leader-designated activities should be enjoyable for group

members. Beyond the pleasure of the interaction, each activity should incorporate critical variables that teach aspects of the group task. The free activity time is a period during which members are allowed to choose their own forms of play, again within parameters set forth by the leaders and using acceptable play materials. During this period, the leaders are involved directly only as needed and as invited by the members. When not playing directly, the leaders are active observers, moving among the members to interpret or facilitate interactions. Leaders are able to teach a great deal about adaptive behavior in this relatively naturalistic situation. The free activity period is thus intended as a time for members to learn more about spontaneous interactions and the issues engendered by such informality in relationships. For some very young, very impaired groups of children, a free activity time is too overwhelming and disorganizing. Children with extremely deficient play skills, for example, severely affected children on the autism spectrum, experience a free choice playtime as painfully bewildering. Such a lack of structure leads mainly to very maladaptive behaviors as group anxiety increases in the face of ambiguity. For such groups, a leader-guided play time is a good substitute. Each coleader leads a separate, developmentally appropriate game or activity for a portion of the group. The group members alternate between the leaders' activities, according to a schedule designated by the leaders. Disorganized youngsters find this type of adult-centered play much more reassuring and enjoyable. As a result, they are able to learn much more than they would otherwise.

Snack Time

Once cleanup from the activity periods is completed, the group should have snack time. Each member should be assigned an ongoing "job" to help with snack, handing out napkins, spreading a tablecloth. The intention of snack time is to provide tangible support to the group, to promote more relaxed interaction and reflection among group members, and to teach members about appropriate informal behavior. Once the food and drink are passed around, the group journal should be brought out. The journal is a written record of the group's work. Members dictate and the leader writes in the journal. Each member is able to contribute what he/she would like to remember about the current group meeting. Leaders are free to add comments. The combined entries are then read back to the group. Afterward, the journal is circulated among members and leaders for each person's signature. In groups too young to write comfortably and quickly, individualized stamps or hand tracings can replace signatures. The journal provides a wonderful written record of the life of the group. Periodically, members refer to earlier entries to answer questions about the chronology of events or the tenure of various members. At other times, members sign nicknames or add comments to express feelings about themselves, previous group members who are missed, or particular occurrences in group. As time permits in the

snack period, groups tend to focus back on their task in a variety of ways. A social skills group, for example, might use the time to tell jokes and rate the humorous value and social comedic skill involved in each joke.

Dismissal

Once snack time is cleaned up, it is time to dismiss the group. This period of the group is typically very tense and overwrought. Having participated in the intense interaction of the group meeting, it is difficult for the members to prepare themselves for separation and return to their individual pastimes. Leaders need to be actively involved in helping the members ready themselves, in maintaining order in the group, and in being reassuring about when the group will meet again. Leaders can help members learn more adaptive ways to manage the ending transition by instituting additional group rituals, providing "social scripts," and modeling appropriate departure behavior. When ready, group members should be returned to their parents or caregivers. In particularly active or disorganized groups, it might be necessary to return the members in shifts separated by 1 or 2 minutes rather than all at once. Leaving in subgroups of two to three members is often more manageable for parents/caregivers and less chaotic in a professional office or clinic setting.

BEHAVIOR MANAGEMENT

Leaders must respect the enormous impact of the particular form of psychopathology, trauma, or skill deficit common to the group members. In dedicating the group to work on grappling with fundamental psychopathology, overcoming significant trauma, or building much-needed skills, the leaders must understand the extreme challenge facing the group as a whole. While every effort should be made to create a group structure that can facilitate accomplishment of a challenging group task, the group should still be expected to falter at times. Through inappropriate behavior, child and adolescent groups often manifest not only their possible presenting problems but also their reaction to the demanding nature of task accomplishment. Because inappropriate behavior is so intimately related to the fundamental clinical core of the group, efforts to manage this behavior should likewise be thoughtfully intertwined with sound, clinical reasoning. Without a comprehensive approach to behavior management, no amount of clinical acumen, theoretical sophistication, or leadership skill will be sufficient to ensure the group's safety, organization, and productivity. Crawford-Brolyn and White (26) and Soo (27) supported the need for careful behavior management in groups for children and adolescents. The five-level approach to behavior management discussed below represents an effort to implement both therapeutic understanding and realistic practicality in managing behavior in a child or adolescent group.

Consideration by Leaders

In the face of difficult, inappropriate behavior, leaders should first think carefully about the communicative intent and underlying meaning of the undesirable behavior. Almost invariably, leaders can either link such negative behavior to the basic problems that led to group admission in the first place or can understand the negative behavior as an expression of the difficulty experienced by the group in attempting to respond to leader interventions. Well-reasoned understanding of the negative behavior constitutes the best foundation possible for effective response by the leadership. As important as this thoughtful consideration is, it should be understood that, on relatively rare occasions, some negative behavior is displayed in group that demands immediate intervention to maintain safety. Quick action should be taken to protect group members and property. Fuller consideration of the meaning of the behavior should follow.

Structural or Procedural Change

Once the behavior has been understood, the leaders should explore the possibility of a structural or procedural change that could address the need being expressed in the negative behavior. A structural change might involve switching from a free activity period to a leader-guided play activity to help the group feel more supported and secure, thereby containing acting-out behavior among very impaired young children. A procedural change might involve escorting group members to and from group in subgroups, rather than in the group as a whole, to reduce stimulation and allow for more organized behavior under closer leader supervision. In most appropriately constructed outpatient or community-based therapeutic groups, most negative behavior can be contained using these two levels of intervention. Realistically, however, not all inappropriate behaviors can be managed so readily. The remaining intervention levels are intended to address greater levels of need.

Verbal Interpretation

Should negative behavior persist despite clear understanding by the leaders and any appropriate structural or procedural accommodation, it is helpful to interpret aloud the meaning of the unwanted behavior. Such verbal interpretation operates in groups much as it does in a dynamically oriented individual psychotherapy. The verbal clarification of the negative behavior illuminates that behavior's communicative intent and/or significance. That intent or significance can then be discussed or acted upon appropriately, relieving the group of the need for continued negative behavioral acting out. Discussion and decisions for group action have the greatest impact if multiple members are involved. Reactions and opinions from the group as a whole

have much more motivational power than input solely from group leaders. Again, in most groups, behavior management usually does not move beyond this level.

Verbal Limit

When undesirable behavior does continue despite taking the above steps, a limit is required. If preliminary levels of intervention have been tried and have been inadequate, leaders should not hesitate to set a verbal limit, reminding the group about appropriate behavior and directing members to remain within acceptable behavioral parameters. It is always most effective to phrase verbal limits in positive terms. Group members will respond best when told what *to do* as opposed to what *not to do.*

Physical Limit

On infrequent occasions, inappropriate behavior persists despite all efforts. On such occasions, a physical limit is mandatory to guarantee the group's safety. For example, unacceptable materials should be taken from members, members may have to move to less desirable physical locations within the group meeting room, or members may have to take a time out. The group should be well informed ahead of time of what limits will be implemented, depending on the need. In the most extreme circumstances, a member might pose such a danger to the group due to uncontrolled acting out or some other condition that he/she must be removed permanently from the group. Such a step should be explained clearly and concisely to the group. This step should be taken only if the danger to the group is pronounced and if no alternative is available. Reluctance in removing a group member is recommended because there is always irreparable damage to the group when a member is removed, regardless of the justifications for the removal. The group usually experiences the loss of a member as an aggressive act by the leaders. Remaining group members worry permanently about potential ramifications and implications of that act. Members scrutinize and inhibit their own behavior because they are afraid that they too will be expelled. Members feel angry toward the leaders and guilty about any negative feelings that they may have had toward the lost member. While explanation and reassurance by the leaders is helpful, the leaders should be prepared to deal with reactions to and memories of the removal of the group member for as long as the group continues to meet.

PARENT INVOLVEMENT

For child and adolescent groups to succeed, parent knowledge and support of the group are essential (28). The nature of parent involvement in group treatment for

children and adolescents varies greatly, however, depending on the population served and on whether the group is in an outpatient or inpatient/residential program setting. For inpatient/residential program groups, parent involvement is relatively distant. Parents are typically informed periodically about their youngster's progress in the hospital or residential treatment program as a whole.

In contrast, because attendance in the outpatient group generally requires parent assistance with transportation and because the outpatient group tends to represent a singular investment of family time, effort, and finances, parents are much closer to outpatient group experiences. Various approaches to including parents in the group therapeutic work have been discussed elsewhere (29). It is most useful to consult closely with the parents in making group admission decisions. A thorough understanding of parental concerns and perspective is necessary to ensure that the group experience, as constructed, is capable of addressing those concerns. Following admission to the group, parent involvement should be managed in accord with the developmental level of the group members. As appropriate, periodic meetings should be held with parents to keep them informed about group progress and the progress of their individual child. Written correspondence is a good alternative to face-to-face meetings to keep parents informed about the group's work. Whenever possible, suggestions based on knowledge gained in the group should be offered to parents to enhance functioning in all the spheres of the child or adolescent's life.

In addition, parents should be encouraged to contact the group leaders at any time with questions or concerns. Group members should be fully aware of the parents' access to the leaders. Managed correctly, this parent-group leader communication is very beneficial to the child and adolescent group members. Members will often request for direct specific communications between the adults to address particular issues. Adult communication should occur outside of the group meeting times, however. In line with the discussion below about boundary management regarding information, parents should be helped to see that direct parental input into the group meetings would likely interfere with the ongoing group process.

LEADERSHIP FUNCTIONS

Group leaders' fulfillment of their role requirements is essential for the group to accomplish its task (30). The group should be able to rely as heavily as necessary on the consistent strength and good judgment of the leaders as it engages in rational work and struggles to pull itself out of more defensive, irrational functioning. Several leadership functions are of paramount importance.

Safety

The single most important leadership function is to ensure the safety of the group as it

works toward task accomplishment. The group leaders must demonstrate a fundamental commitment to physical and emotional safety in the group. A coherent approach to behavior management, such as the one outlined earlier, should be implemented to ensure group safety. Without such a guarantee, it would be unfair to maintain expectations for intensive therapeutic work of any type.

Primacy of Cotherapy Relationship

From a clinical perspective, to ensure physical safety, mainly in groups of younger or more disturbed individuals, to process adequately the enormous amount of clinical information generated in each group meeting, and to have a dyad within the group that can be used as a model of a functional interpersonal relationship, it is always advisable for a group to be led by two coleaders. Dies (31) underscored, however, that empirical support was lacking for the benefits of group cotherapy. In view of the fact that cotherapy is utilized widely regardless of the status of empirical support, both Dies (31) and Riva et al. (30) emphasized the need for careful management of the cotherapy relationship to enhance group functioning. If the group is to reap the benefits of the cotherapy relationship, however, this relationship must be fostered and supported carefully.

The coleaders must communicate openly and honestly regarding their work together. This communication should occur both during regularly scheduled formal meetings as well as in more informal moments while the work proceeds. The leaders should choose a mutually acceptable way of sharing the leadership work. There are many possible, equally productive choices available. Leaders should make a choice based on the task of the group, differential leadership skills, individual preferences, interpersonal style, and relative professional status/responsibilities. One commonly made choice is for one leader to assume managerial responsibilities, that is, setting the agenda, being the most vocal, leading activities, introducing topics, while the other leader remains quieter, focusing intently on emotional reactions within the group and articulating those as appropriate. While no one choice is correct for all coleader pairs, a successful choice must be genuinely acceptable to both leaders and must be made based on leadership strengths rather than weakness or fear of carrying out specific leadership functions.

Leaders should know that they always have the freedom and responsibility to speak directly to one another regarding group matters in the presence of the group. To gain needed support in the face of challenging group interactions, to articulate an issue relevant to the group's work, to ensure full knowledge and cooperation between the leaders regarding a particular intervention, to resolve differences, and to model reciprocity between people, there is no better method than public communication between leaders. Even when the group may appear to be ignoring the leaders' conversation, the group in fact often listens intently and makes productive

use of the interaction. Unlike genuine points of disagreement or difficulty in coleading, coleaders will sometimes become embroiled in disagreements or stuck in generalized tension between themselves but be unable to identify the actual source of the problems. Such disagreements and tension should be understood as unspoken, empathic responses to the group. The coleadership relationship often becomes the vehicle for expression of group conflicts, wishes, or needs that the group cannot yet verbalize directly. When the coleader pair finds itself in such a quagmire, first it is best to discuss the problem fully within the pair. Then, it is most useful to offer a developmentally attuned interpretation to the group and go on to help the group identify, understand, and grapple with the issue facing it. Without such exploration between the leaders, it becomes all too easy for the negativity between the coleaders to become so firmly and unpleasantly entrenched that all the work of the group is stalled.

Protection of Group Structure and Boundaries

To provide the group with sufficiently strong support in approaching its task, the third most important function for the leaders is to safeguard the structure within and boundaries around the group (31–34). The members need to be able to rely on predictability and reliability in the group's life if they are to be able to muster the strength to continue with rational work. The leaders must make sure that the group agenda is adhered to at each meeting, that limits are set and implemented in a consistent fashion, and that appropriate material resources are available to the group. The leaders must also maintain firm time, space, informational, and membership boundaries around the group. Group meetings must begin and end promptly, regardless of extraneous demands/events or enticing clinical material that is presented in the last few moments of a group's scheduled meeting. The group must have a dedicated space, in which the group's privacy can be respected for the duration of each group meeting. Leaders should take care to conduct the group's business only within the group's designated space. Entering into group discussion or play in a waiting room or hallway, no matter how critical or tantalizing the material may seem to be, weakens the group's potential reliance on the leader because the work cannot be pursued adequately in a more public and therefore less reliable setting. As the group becomes a meaningful entity for its members, the group should set a policy about how information will flow into and out of the group. Salient facets of this policy include member responsibilities to maintain group confidentiality, procedures for taking up information communicated by parents, and procedures to be followed by leaders in introducing essential issues that members might be uncomfortable about bringing up themselves. In firmly led discussions, groups are usually well able to make rational policy decisions about the flow of information. Leaders always retain veto power should policy decisions be inappropriate. Finally,

the leaders must maintain clear distinctions between who belongs to the group and who does not. For both clinically relevant and for defensive reasons, members and their families often invite leaders to allow other people to attend group meetings or to join in group activities. These invitations should be declined politely but firmly in the interests of maintaining the group's integrity and reliability.

Distinction between Leader and Member Roles

Groups that are led with sufficient strength and reassurance are rarely democracies. To provide adequate support and guidance, leaders should retain authority and responsibility while continuing to convey respect and appropriate clinical sensitivity toward the group members. An important aspect of such authority and responsibility is maintenance of the distinction between the roles of members as opposed to leaders. Leaders should reserve the right to make the physical environment as comfortable as necessary to allow them to concentrate fully on their leadership tasks. Decisions about self-disclosure, participation in activities, and behavioral demands should be made in relation to the task of the group rather than to any notion of "fair play" or assumed obligation to do "themselves" whatever is asked of the group members. While such a distinction between leader and member roles may seem autocratic in the abstract, in clinical practice this type of distinction serves very well the clinical work of the group. Group members understand that they can rely heavily on the leaders; they do not feel oppressed by them.

Management of Relationship between Group and Organizational Base

Many clinical groups for children and adolescents are offered under the auspices of a clinic, hospital, or child guidance center. In such settings, factors such as billing practices, physical space, interaction with organizational staff and other patients/clients, attendance policies, privacy, personnel, material resources, and the tone of the organizational atmosphere all have a potential impact on the life of the group. It is the responsibility of the leaders to manage this relationship between the group and its surrounding organization. Although the group leaders rarely if ever have the authority to control the larger organization in the interest of their group, the leaders can and should articulate the needs of the group within the larger organization, advocate strongly for the necessary resources of all types, intervene if there are potentially disruptive interactions between group members and/or their parents and representatives of the organization, and facilitate the group members' transactions within the larger organization. When group leaders abdicate this managerial aspect of their leadership responsibilities, premature departure of members and group dysfunction are common outcomes. Fulfillment of these

leadership responsibilities, on the other hand, helps to further protect the group and models adaptive behavior for the group members.

Support through Group Transitions

Some of the most challenging experiences in groups involve major transitions. Changes in coleadership, new members joining a group, either planned or abrupt terminations of an individual's membership in the group, or changes in meeting location are examples of common transitions through which groups must sometimes navigate. At such times, leaders must be very conscious, deliberate, visible, and direct in providing adequate, developmentally attuned information about what the group should expect, reassuring the members about continued leadership and support available to the group, and helping the group articulate their reactions and concerns regarding the transitions. As at all other times in the life of the group, leaders should facilitate the group's movement through any given transition in a manner consistent with the task of the group. The group should be encouraged to marshal skills consistent with its task as it manages the transition.

SPECIAL APPLICATIONS

As discussed throughout this chapter, group treatment can be directed at a wide variety of issues facing children and adolescents. Two particularly useful special applications of this treatment modality involve provision of support for youngsters contending with HIV/AIDS in their families (35,36) and teaching of social skills to youngsters on the autism spectrum (37).

HIV/AIDS Support Groups

In the early days of the HIV/AIDS pandemic, many children faced the rapidly worsening illness and imminent deaths of parents and other loved ones in their families. As medical treatments improved, many children had to learn to contend with HIV/AIDS as a more chronic illness in their families. At any time, supportive group experiences structured and operated in the manner discussed above offer a great deal to children affected by HIV/AIDS. The basis for admission to such a group has to be some family acknowledgment that HIV/AIDS has touched the family. Group members must be able to tolerate learning that the group is designed for youngsters who are facing HIV/AIDS in one or more loved ones. Almost always, youngsters are already aware of the presence of HIV/AIDS in their families even before direct adult acknowledgment is made. Their awareness and understanding are often covert and incomplete, however. Open recognition and admission to the group help to give an honest name to what has often been a burdensome, quasisecret in the family.

Participation in the group facilitates a fuller understanding of the facts and implications of HIV/AIDS in the family. Without the burden of secrecy, children and adolescents can feel less afraid to learn how to cope with their situation.

Beyond naming a previously known but unacknowledged phenomenon, membership in an HIV/AIDS support group challenges the sense of isolation that frequently accompanies dealing with a devastating illness. In the case of HIV/AIDS, this isolation often stems from shame and guilt about the nature of the illness itself. The group's existence testifies to the fact that many individuals share the problems associated with HIV/AIDS. Such testimony diminishes individual shame and guilt, thereby relieving the loneliness of coping with the disease, and assists the members as they tackle each difficult phase of HIV/AIDS with their loved ones.

A third benefit of an HIV/AIDS support group is that it offers the members a set of reliable interpersonal relationships that are not endangered by the disease. The group offers closeness and intimacy that are invaluable for the members' sense of interpersonal relatedness. In doing so, the group provides a framework in which more normative psychosocial development can proceed.

Finally, the group experience also reminds members that there is life beyond HIV/AIDS. The group demonstrates that life events and transitions can relate to a host of factors, both positive and negative, unrelated to HIV/AIDS. One particularly striking example involves leadership changes. As with any clinical endeavor, HIV/AIDS support groups must contend with the departure of leaders from time to time due to career changes, assignment of different responsibilities, pregnancies, etc. In this type of support group, members are often shocked when a farewell is prompted by something other than illness and/or death. Enduring the sadness of a parting but knowing that the missed person is going onto another satisfying life stage opens up countless possibilities for the members themselves as they begin to contemplate their own futures.

HIV/AIDS support groups for children and adolescents present two main challenges to leaders. First, leaders must be able to tolerate extremely sad information. Without resorting to defensive minimization or avoidance, leaders must accept and be comfortable exploring devastation in the lives of the group members. Often, to demonstrate concern and to provide assistance, carefully modulated participation in sad events, such as funerals in the families of group members, is also required as part of full group leadership.

Second, leaders must learn to cope with often dramatic acting-out behavior in the group. In many instances, the family's experience of HIV/AIDS is part of a constellation of psychosocial problems. Together with the stress of HIV/AIDS, this constellation of problems contributes frequently to the development of significant behavior problems that challenge the safe operation of the treatment group. Leaders must learn a variety of strategies to meet such behavioral challenges. Relevant strategies have been discussed in Gossart-Walker and Moss (35,36).

Autism Spectrum Social Skill Groups

Social, communication, and peer relationship problems are the core deficits of individuals with diagnoses on the autism spectrum. Accordingly, group treatment is an ideal setting in which to teach social, interpersonal skills to be implemented in real-life situations (38). The group serves as a microcosm in which all the social demands of everyday life come into play. Unlike everyday life, however, leaders of the social skills group are present to instruct and to orchestrate helpful peer interactions.

Social skill groups for individuals with autism spectrum disorders are usually one of two types. The first is curriculum based. Such a group is generally time limited and follows a set plan for teaching discrete social skills. Such a group is excellent for lower-functioning individuals on the autism spectrum. For such group members, learning such skills as how to greet another person or to say thank you when appropriate is an impressive accomplishment.

The second type of social skill group is more naturalistic. Such a group is generally long term or open ended. While structure remains essential, as discussed above, this type of group capitalizes on the naturally occurring interpersonal interactions within the group as the source and object of instruction. Naturalistic social exchanges are used to teach about more fluid social functioning. Given its more interactive nature, this second type of group is better suited to higher-functioning individuals with autism spectrum disorders.

Regardless of level of functioning or type of group, two characteristics are essential if a social skill group is to be useful for autism spectrum members. First, group leadership and instruction have to be concrete, blunt, direct, and down to earth. Subtler, inquiring, insight-oriented forms of leadership and instruction would be far too vague and bewildering for individuals with autism-related disorders. While professional standards demand that leaders refrain from being rude, leaders in this sort of social skill group should understand that their responsibility is to use their own individual behavior, their interaction with one another, judicious self-disclosure, and all of their teaching skill to provide the most direct instruction possible. As a leader in a group for autism spectrum individuals, it is impossible to be too blunt or too concrete.

Second, for the group to be of maximum benefit, it should include exposure to peers who are not on the autism spectrum. Only with some diversity is it possible to provide socially grounded, realistic reactions to and modeling for the members on the autism spectrum. If composed solely of individuals on the autism spectrum, the group risks having no counterbalance to the social idiosyncrasy that characterizes autistic disorders. In turn, those on the spectrum can often bypass defensive behavior on the part of other members and speak directly to the problems that brought them to the group. Exposure to diverse individuals can be accomplished by admitting

members with a range of diagnoses to the group. While their diagnostic status can vary, with only some of them on the autism spectrum, all of the group members should have social deficits. This exposure can also be accomplished by admitting only members on the spectrum but incorporating the services of typical peers as role models for the group members. Minimal training should be given to typical peers so as to maximize their capacity to model true-to-life peer behavior rather than pseudoadult, therapist-like behavior. Typical peers should receive enough basic information about the autism spectrum to feel reasonably comfortable, followed by encouragement to behave as naturally as possible.

Social skill groups are capable of facilitating significant improvement among children and adolescents with autism spectrum disorders. Many of the group members are able to fit in much better at school, develop a social life suited to their particular needs and wishes, and display much more socially appropriate general behavior. Enthusiasm about the groups must be realistic, however. Social skill groups are not powerful enough to change the fundamental organization of an autism spectrum disorder. Even successful members may remain idiosyncratic.

INDICATIONS AND CONTRAINDICATIONS FOR GROUP THERAPY

The issue of who would best benefit from group treatment is tied intimately to the identified task of the specific group. Appropriate admissions are those individuals in need of work on the group's task. Beyond this relatively simple statement at the level of group content, however, there are also broader concepts that should guide admission decisions. Group treatment would be indicated for reasons and under conditions such as those discussed directly below.

First, some mental health difficulties and aftereffects of traumatic experience burden affected individuals with a sense of isolation and culpability. Affected individuals may feel somehow to blame for calling down on themselves damaging experiences that paradoxically confirm negative self-assessments. Individual or family treatments in such situations, regardless of how expertly implemented, rely on discussion or other indirect methods to challenge the negative personalization. In contrast, by definition and by its very existence, a treatment group combats the isolation that so often oppresses children and adolescents struggling with developmental, psychological, and behavioral disorders (39). Inclusion in a group with others who are grappling with similar difficulties challenges individual self-blame and invites the individual to join with peers in shared, instrumental attempts to cope and overcome.

Second, whether due to innate personality characteristics, acquired interpersonal experience, or the cumulative effect of multiple therapeutic relationships, some people have the capacity to maintain excessive psychological distance between

themselves and an individual therapist. Such individuals can insulate themselves from true consideration of even the best therapeutic overtures, plans, or interpretations. It is much more difficult, however, to ward off the power of an entire group process. Varied input from fellow group members often spurs this type of individual on toward greater therapeutic progress. Conversely, some more psychologically fragile individuals find the intimacy of one-to-one or even family therapy to be overwhelming. The shared relationships of a group treatment dilute the intimacy sufficiently so that therapeutic input becomes tolerable (40).

Third, some problems that are presented to mental health practitioners not only benefit from but also require the presence of more than a therapist–patient dyad for the most efficacious intervention. Most prominent among such problems are deficits in social/peer functioning, such as those that afflict individuals on the autism spectrum, and conditions requiring psychoeducational support (chronic medical illness, family disruption). Unlike more intrapsychic problems or personal psychopathology that often play themselves out in a dyadic therapeutic relationship, thereby lending themselves to psychological interpretation and redirection, peer difficulties and psychoeducational support needs may rarely be as evident in a one-to-one setting. As a result, a therapist–patient dyad would be reduced to talking *about* rather than experiencing immediately the most relevant situations. In contrast, tackling problems with peer relationships in the social environment of the group allows for enactment of and immediate intervention in the problems that interfere with the group member's more optimal functioning in the real world. Addressing needs in the group for guidance regarding logistical organization, social embarrassment, and fear about the future offers maximum support to group members in need of coping assistance. Both the fundamental experiences of group membership, as well as the content of the group's work, have a beneficial effect.

There are three main principles that argue against inclusion of an individual in a group. First, while group treatment can be helpful to impulsive children and adolescents, no individual should be permitted to join a therapeutic group if that individual poses a substantial threat to the basic safety or health of the other group members. Thus, impulsive children and adolescents whose poorly controlled acting-out takes the form of extremely aggressive or excessively risk-taking behavior, are inappropriate candidates for group therapy. This contraindication needs to be taken very seriously since, as noted earlier, physical and psychological safety is the fundamental guarantee that group leaders must provide to the group if any meaningful work is to occur. Prospective members who pose a safety threat to the group should be referred to other treatment modalities or for consultation, as appropriate. Many times, addition or modification of psychiatric medication can alter sufficiently the troubling behavior and thereby allow for reconsideration of an individual's group admission.

The removal of a group member by the group leaders is a related issue that merits

attention in the context of indications and contraindications for group treatment. Often, leaders focus on one child or adolescent as the primary source of difficulty in a group. Typically, this is the group member that presents the greatest challenges in behavior management. Many times, leaders wish or proceed to remove this group member in the interests of more meaningful group work. For two main reasons, such a removal is almost never successful. First, as stated before, remaining members become angry and anxious about the possibility that they, too, will be required to leave. Behavior in the group is impacted as the remaining members enact their angry anxiety in the forms of limit testing, excessive inhibition, or open accusations directed against the leaders. Second, theoretical principles argue that the offending member was carrying out a function or making a communication relevant to the group's work, regardless of how seemingly inappropriate that function or communication seemed. As a result, it is usually the case that a previously well-functioning group member takes over the ousted member's more provocative role. The difficult behavior subsides only when the group has dealt with its meaning, in ways discussed above, and then moves onto new aspects of its task.

From time to time, though, the decision to remove a group member is actually clinically indicated. This comes about most often when new, more disturbing diagnostic information becomes manifest as the group proceeds or when an individual's status changes in such a way that poses a risk to the group. Then, the leaders have no choice but to carry out a planned termination in the most open, thoroughly discussed, and fully anticipated way possible. Regardless of the reasons for member removal, the group's negative reaction to removal of a member persists for a substantial amount of time, in some instances for the remainder of the life of the group. Even when the subject is dropped temporarily from discussion, it resurfaces at stressful times in the group's work. Leaders must be prepared to work through the issue of the member's removal on multiple occasions. Partly because removal of a member is so devastating to a group, admission decisions should be made as carefully as possible to do everything possible to avoid the necessity of member removal.

Second, as mentioned previously, groups do not operate effectively if there is only one member representing a key variable (one female in a group of males, one member of a particular race or ethnicity in another homogenous group, one psychotic individual in a group in which no one else's diagnosis involves impairments in reality testing). A single representative along a key dimension promotes loneliness, isolation, and scapegoating. Should an individual be an appropriate admission on other inclusion criteria, admission should be deferred until a similar member can be admitted at the same time.

Third, there are some children and adolescents who need and would benefit from work aimed at the stated task of a given group but who have never before identified or explored their relevant needs. Abused children and adolescents who have never

acknowledged the abuse in any way would be examples of this type of prospective group member. While group participation at some point might be the treatment of choice for such children and adolescents, a group is too large, interpersonally diffuse, and unpredictable to be the setting in which an individual takes the first step toward confronting their traumatic history. These children and adolescents should receive more individualized services first to ready them for group participation, as needed and as appropriate.

TRAINING AND SUPERVISION OF GROUP THERAPISTS

Many authorities have addressed training needs as they relate to group therapy practitioners (3,41–43). Azima (44) also addressed the impact of group work on the therapist's own functioning. The foundation of training as a child/adolescent group therapist is the same as the foundation of training for any mental health clinician. Regardless of discipline, the practitioner should have thorough knowledge of child/adolescent development, psychopathology, and a range of therapeutic interventions. The therapist should be comfortable with a wide variety of individuals and diagnostic categories. With this type of foundation, an interested mental health professional would be well able to pursue more specialized training in group approaches. Ideally, the training should be three-pronged. Simultaneously, the practitioner should receive didactic training in the history, theory, and practice of group therapy with children and adolescents, colead a group with an advanced group leader, and receive ongoing clinical supervision of the cotherapy. The didactic experience places the group work in an intellectual and historical context that deepens and solidifies the work, distinguishing clinical group endeavors from more casual group experiences for young people. The coleadership provides immersion in and illustrations of the material discussed in the didactic setting. Finally, the ongoing supervision articulates the nuances of the group life and of the cotherapy relationship, enhancing the trainee's learning and extending his/her clinical skills. When ready, the trainee can assume greater independence in group leadership. In this regard, MacLennan (45) delineated specific training required to conduct groups at particular age and developmental levels while Soo (43) called for strengthening fundamental clinical skills to facilitate successful group leadership.

It should be noted that group supervision/consultation is often very helpful even for well-established, talented group therapists. The supervision can, of course, assist with therapeutic questions and problematic group issues. Beyond the immediate resolution of treatment problems, however, expert group supervision can elevate the leaders' understanding of the group's life. In the press of day-to-day group management demands and the challenges posed by diverse diagnostic needs among group members, it is often understandably easy for group leaders themselves to lose sight of the group historical context or the theoretical concepts that underlie current

group experiences. Consultation and guidance from an expert who is somewhat removed from the meeting-to-meeting stimulation can have a clarifying, instructive effect for the group leaders. Critical variables and best practice recommendations regarding supervision of group leadership are well summarized by DeLucia-Waack and Fauth (46).

EFFICACY AND CURRENT RESEARCH

For a long time, there has been a broad consensus that group treatment is beneficial for specified populations of children and adolescents (47). To a great extent, this consensus rested originally on clinical observations and professional experience. Early research efforts were qualitative, narrative reports. While often rich in clinical insight and technique, such efforts were subject to criticism regarding validity, reliability, relevance to larger populations, and cost effectiveness. Mirroring broader psychotherapy research efforts and to address such criticism, group therapy research attempted to move more in the direction of sound, empirical studies (48). A number of studies and reviews demonstrated comparable effectiveness of group and individual therapies (33,49–51). Effective application of group therapeutic techniques to a wide variety of populations has been documented (24).

Yet many questions remain. The full potential efficacy of cotherapy needs to be explored (30,31). The most useful integration and application of theoretical perspectives need to be articulated (6). In addition, the complex interaction among group structure, process, leadership style, and outcome needs further study. Precise linkage of the most curative processes in group therapy with specific populations of children and adolescents stands as most prominent among current research and clinical questions (24,28). New instruments measuring such variables as group cohesion have been developed to facilitate comparability across more rigorous research studies. Leaders in the field have called for shared use of these new instruments to promote comparability across studies (48). While a great deal remains to be done, strong interest in and need for group therapy with children and adolescents exist throughout the medical and mental health communities (52). It would be reasonable to expect a body of research to emerge that expands greatly our knowledge of group treatment, integrates standards for sound empirical research with recognition of clinical complexity, and thereby guides efforts in efficacious ways.

CHAPTER 6.2.7 ■ FAMILY THERAPY

G. PIROOZ SHOLEVAR

INTRODUCTION

Since the publication of the last volume of this textbook, family therapy has continued to expand its scientific base and theoretical evolution. Evidence-based programs primarily delivered as home-based, family-centered interventions in the community have continued to produce impressive results with adolescents with conduct disorders and substance abuse. Family interventions also have been applied systematically in controlled studies to a very broad range of clinical disorders of children and adolescents.

The fundamental theoretical concepts and technical interventions developed by pioneers in family systems and psychodynamic therapy have been adopted by the contemporary generation of family therapists who apply them in a multidimensional and ecologic manner, incorporating the characteristics of the children, their peer group, community, and broader culture. This broad framework has allowed the incorporation of other treatment modalities, such as cognitive-behavior therapy (CBT) and pharmacotherapy, which has significantly enhanced treatment effectiveness. A more flexible approach to involving parents has enhanced engagement in treatment, retention, and treatment outcome. Partly in response to these developments, NIMH has encouraged the use of family interventions in investigative projects; more than half of NIMH-funded intervention proposals and programs include a family component (1).

DEFINITION

Family theory focuses on human behavior and psychiatric disturbances in the context of interpersonal relationships (2–4). This theory forms the basis of family therapy, which is an umbrella term for a number of clinical practices that treat psychopathology within the context of family systems rather than individuals. Interventions are designed to effect change in family relationships rather than in an individual (2,5). This approach is based on observations that symptomatic behavior appears in individuals involved in certain dysfunctional processes within their families or with other significant persons. Conversely, positive family interactions such as effective parenting practices, emotionally nurturing family environments, and secure attachment relationships are associated with normative child development, healthy functioning, and serve as protective factors against emotional disorders (6).

Family theory considers the family as an interpersonal system with cybernetic qualities. The relationships among the components of the system are nonlinear (or

circular); the interactions are cyclical rather than causative. Complex interlocking feedback mechanisms and patterns of interaction among the members of the system repeat themselves sequentially. Any given symptom can be viewed simply as a behavior functioning as a homeostatic mechanism that regulates family interactions (7).

The family system is nonsummative and includes the assets and dysfunctions of the individuals as well as their interactions (8). A person's problems cannot be evaluated or treated apart from the context in which they occur and the functions that they serve. It is assumed, therefore, that an individual cannot be expected to change unless the family system changes (8). Treatment addresses the behavioral dysfunctions as a manifestation of disturbances within the entire family relational system; the role of the total family in aiding or in sabotaging treatment is the focus even when a distinct diagnosable psychiatric illness is present in one of the family members.

The goals of family therapy as a psychotherapeutic approach are as follows (3):

- Explore the interactional dynamics of the family and their relation to psychopathology.
- Mobilize the family's internal strength and functional resources.
- Restructure the maladaptive interactional family styles.
- Strengthen the family's problem-solving behavior.

The term *family therapy* has been expanded to include family intervention, a broader array of procedures. It subsumes a large number of clinical practices based on a variety of theoretical concepts with explicit focus on altering the interactions among family members and subsystems with the goal of improving the functioning of the family as a unit, its subsystems and members. Treatment of disturbed individuals as well as dysfunctional relationships can be achieved through family interventions (3,4). Improved functioning in parental and parent/child subsystems is a fundamental goal in treatment of children and adolescents.

HISTORY

Family therapy and conjointed treatment of families emerged in the late 1940s and early 1950s. The towering figures in the field were Nathan Ackerman, Gregory Bateson, Murray Bowen, Bell, Theodore Lidz, Don Jackson, Jay Heley, and many others. Family therapy with a focus on children and adolescents was introduced by Carl Whitaker, Salvadore Minuchin and more recently by David and Jill Scharff, Joan Zilbach, and others. A detailed description of the history can be found in recent literature (9,10).

In the late 1960s, Minuchin in collaboration with Montalvo and Haley established the Structural School of Family Therapy. The structural approach reached its height

in theoretical development by defining the term *psychosomatic families*—the families of patients with anorexia nervosa and other psychosomatic disorders (11). The structural approach has been applied extensively to families of children with behavior disorders (12).

An underappreciated approach to family therapy with adolescents and children was attempted by the Multiple Impact Therapy group (MIT) in Galveston, Texas (13). The novel intervention by this group included 2 days of family therapy by a number of professionals who alternated their work with different family members during the therapeutic encounter. They classified the families according to the disorders of the adolescents and children, mostly oppositional/defiant and conduct disorders.

INDICATIONS AND CONTRAINDICATIONS

An apparent and clear indication for family therapy is open and stressful conflicts among family members, with or without symptomatic behaviors in one or more members. Family therapy also can be applicable when there are covert problems within the family, which can give rise to dysfunctional behavior in one or more family members, or when other family members covertly support and perpetuate the disorder. Recognizing covert family interactional problems coexisting with overt dysfunctions in one or more family members is the specific contribution of the field of family therapy. Recently, family interventions have been used extensively with externalizing adolescent disorders and substance abuse.

Contraindications to family therapy are relative rather than absolute. They include discussing long dormant, charged, or explosive family issues with the whole family before the family commits seriously to treatment. Another relative contraindication is discussing stressful situations with the family when one or more members are severely destabilized and require hospitalization. Insufficient expertise in family therapy relative to a high level of resistance and defensiveness in the family can result in a counterproductive treatment course. Lack of knowledge of child development and psychopathology can render family intervention with children and adolescents equally unproductive and result in missed therapeutic opportunities.

MODELS OF FAMILY THERAPY

The diversity of models of family therapy raises questions about the common ground among family therapies. The pioneers in family therapy focused on different dimensions in the family system, and to some degree, these different focuses reflected unrecognized differences among patient populations treated by the early family therapists. Although family therapists adopted divergent paths, they ignored the likely

conclusion that different approaches to family therapy are closely linked to family characteristics commonly observed in different disorders.

Different models of family therapy are applicable to various patient populations. The intergenerational family therapy models are particularly applicable to families whose members have longstanding disorders and have not negotiated adequate separation and differentiation between the generations (14,15). Structural and strategic family therapies are particularly applicable to families encountering a crisis situation in which there has been adequate separation from previous generations and a reasonably satisfactory precrisis adjustment in the nuclear family. Behavior family therapy is particularly applicable to marital problems and children with chronic conduct disorders. Psychodynamic and experiential family therapies are helpful to family members with narcissistic vulnerability and a broad range of personality and neurotic disorders who have maintained a relatively adequate level of functioning but find little enjoyment in their lives. An emerging array of family-based interventions attempt to reverse the disintegrative processes in chronically and seriously disordered families effected by abuse, neglect, and placement of the children outside of the family.

Each model of family therapy includes different theoretical concepts and techniques. Some models of family therapy can be grouped based on their similarities. The major models of family therapy, their core concepts, goals, and approaches and techniques, are summarized in Table 6.2.7.1.

Structural Family Therapy

Structural family therapy was developed by Minuchin in collaboration with Montalvo and Haley and applied to children and adolescents with acute behavioral problems and eating disorders. The foundational theoretical concept in structural family therapy is boundary. Clear and flexible boundaries are characteristic of functional families. Enmeshed and disengaged boundaries describe families with excessive intrusiveness or unavailability to one another, respectively.

Structural family interventions emphasize establishing boundaries within the family through the decisive and sensitive actions of the therapist. Family tasks and homework assignments further enforce this process. Methods of “joining” the family allow the therapist to join the family and shift family members’ positions to disrupt dysfunctional patterns and strengthen parental hierarchies. Clear and flexible boundaries are established in the session, and the family is encouraged to search for alternative interactional patterns.

Structural family therapy has been used to treat eating disorders, particularly anorexia nervosa in children and adolescents. Its effectiveness in treating psychosomatic disorders and behavioral problems has been proven through numerous case reports and observations, as well as family outcome studies (11).

Strategic Family Therapy

Strategic family therapy emphasizes the need for a strategy developed by the family therapist to intervene in a family's efforts to maintain homeostasis by adhering rigidly to dysfunctional family patterns and symptoms. Strategic family therapy, like psychodynamic family therapy, has a well-articulated approach to address the resistance within family systems. Dealing with resistance, particularly in the family's response to the therapist's interventions, requires innovative methods. One technique, paradoxical intervention, attempts to reduce resistance and enhance change in the family structure and interactions by discouraging change. Paradoxical interventions facilitate the therapist's joining the family with minimal resistance to restructure the family's interactional system.

Strategic interventions are based on identifying a family's "rules"—the metacommunicational patterns that underlie symptomatic behaviors. These interventions are applied through directives and homework assignments practiced between sessions. The homework can be a logical, straightforward approach to the behavior or a seemingly illogical, paradoxical approach such as "prescribing the symptom," a technique requiring family members to do and acknowledge what the family has been doing all along to undermine interactional patterns by supporting the family's communicational pathways. Family life-cycle passages are considered important because they reveal inflexibility in the family's structure that makes the familial response to internal and developmental demands difficult.

The strategic approach of Haley (8) and Madanes (16) emphasizes the importance of strengthening the parental alliance to deal effectively with the symptomatic and challenging behavior of the children. Power struggles between family members and subsequently between the therapist and the family are the focus of treatment.

TABLE 6.2.7.1

MODELS OF FAMILY THERAPY

Model of Family Therapy	Core Concepts	Goal	Strateg
Structural Family Therapy Minuchin et al.	• Generational hierarchy • Boundaries and Subsystems • Flexibility of system for: a. Autonomy and interdependence b. Continuity and adaptive restructuring to fit changing internal and external demands	• Symptoms result from current family structural imbalance: • Enmeshed or disengaged styles • Maladaptive reaction to changing demands (developmental, environmental) • Defuse generational hierarchy and boundaries	• Inter • Reor • Shift to ba • Strer • Rein bour • Mobi alteri
Strategic Family Therapy Milton Erickson Jay Haley	• Repeated patterns of interaction • Power/control struggles • Flexibility	• Symptom is a communication embedded in interaction pattern • Problems; symptoms are	• Resc throu • S • In

Cloe Madanes Paul Waltzlawick John Weakland	• Large behavioral repertoire for: a. Problem-solving b. Life-cycle passage	maintained by: a. Unsuccessful problem-solving attempts b. Impasse at life-cycle transition c. Rigid view; paucity of alternatives	cl se • S pc • P
Solutions-focused Steve de Shazar et al.	• Focus on solutions, not problems • Disregard "resistance" • Inattention to origin of problems	• Creation of solutions • Presolve presenting problems	• "Exc • "Mira • Copi • Clier
Bowen Family Systems Murray Bowen, Micheal Kerr, Philip Guerin	• Differentiation of self • Triangulation • Transmission of symptoms across generations • Family emotional system • Emotional cutoffs	• Increased differentiation • Detriangulation • Improved ability to manage anxiety • Resolution of cutoff	• Use • Ther • Educ Multi proc
Psychodynamic-Psychoanalytic Nathan Ackerman David and Jill Scharff Helm Steirlin Emotionally focused Therapy Susan Johnson Leslie Greenburg	• Projective identification • Interlocking conflicts and defenses observation • Object relations • Projective identification • Splitting • Scapegoating problem • Attachment disorders	• Enhance awareness and self • Enhance empathy • Improve insight • Disentangle interlocking alliance pathologies and resistances • Interpretation • Differentiation of Attachment vs. defensive feelings	• Tran cour • Crea • De-e • Emp
Evidence-Based Family Therapies **Parent Management Training (PMT)** Patterson et al. Forehand, McMahon et al.	• Negative reinforcement of maladaptive behaviors • Ineffective/unskilled Parent management Interventions • Coercive family processes	• Establishment of effective parent management techniques • Promotion of prosocial behaviors in children • Reduce coercive interactions	• Pare pare • Beha with • Prob com • Inten
Functional Family Therapy (FFT) Alexander et al. Sexton T	• Defensive interactions • Lack of supportive interaction • Nonfunctional Dysfunctional/family patterns	• Address the function of symptoms in family interaction • Enhance supportive interactions • Reduce defensive interactions	• Enha funct
Multisystemic Therapy (MST) Henggeler et al.	• Multisystemic dysfunctions on family, peer group, school and community level	• Multisystemic problem-solving	• Inten inter • Trair probl syste
Multidimensional Family Therapy (MDFT) Liddle et al.	• Multidimensional/multisystemic dysfunctions on family, individual, school, community levels	• Multisystemic/multidimensional intervention on family, individual, peer group and community level	• Struc grou inter • Multi probl
Behavioral Patterson et al. Forehand et al. Falloon	• Adaptive behavior is rewarded; maladaptive behavior is not • Exchange benefits outweigh costs; reciprocity • Communication and problem-	• Family attention and reward • Alter deficient exchanges (e.g., coercive, skewed) • Correct communication deficits	• Char reinf • Rew mala • Com

	solving ability • Flexibility		skills
Psychoeducational McFarlane Carol Anderson	• Successful coping and mastery of developmental challenges: a. Caregiving in chronic illness b. Skill in family relationships and community living skills • Stress-diathesis model of Biologically based disorders	• Reduction in normative and nonnormative stresses (e.g., in couples; relationships, parenting, remarriage, adverse life events)	• Infor socia a. Fa ch b. S c. M ch

Partially adopted and significantly revised from Steinglass P: Family therapy. In: Kaplan P, Saddack B (*Textbook of Psychiatry*. 6th ed. Baltimore, MD, Williams & Wilkins Publishers, pp. 1838–1847, 1995; a Family and couple therapy. In: Saddock B, Saddock V (eds): *Comprehensive Textbook of Psychiatry*. & Wilkins, Baltimore, MD, pp. 2157–2167, 2000.

SOLUTION-FOCUSED THERAPY

Solution-focused therapy concentrates on the “exceptional solution” repertoire already practiced by the patients to deemphasize their problem-saturated outlook and enlarge the application of such solutions. The therapeutic effectiveness is enhanced by shifting the focus to the “solution” rather than the “problems” (10,17).

PSYCHODYNAMIC FAMILY THERAPY

Psychodynamic family therapy emphasizes individual maturation, personality development, early childhood experiences, and resolution of symptoms and conflicts in the context of the family system. Common theoretical concepts of psychodynamic family therapy include projective identification, shared unconscious conflicts and defenses, intrafamilial transference reactions, dyadic and triadic family transferences in treatment, and a host of object relations psychoanalytic concepts, such as holding environment and empathy.

BEHAVIORAL FAMILY THERAPY

Behavioral family therapy applies the principles of positive and negative reinforcement to the family unit with the goal of enhancing reciprocity and minimizing coercive family processes. Coercive family processes generally are in the form of punishment, avoidance, and power play. Enhancing communication and problem-solving skills in the family is emphasized and punishment is discouraged.

Contemporary behavior family therapy is based on social learning theory and has been applied in the form of parent management training (PMT). The parents and children are taught environmental contingencies (positive and negative reinforcement, reward and punishment) which shape behavior. Strong attention is paid to enhancing

prosocial behavior.

Behavior family therapy can be combined with communication and problem-solving training.

PSYCHOEDUCATIONAL FAMILY INTERVENTION

Psychoeducational family intervention based on stress-diathesis theory attempts to enhance family adaptation primarily through informing the family and patient about the nature of psychopathology in psychiatric disorders. The family and patient also receive detailed information about the treatment process and outcome. Psychoeducational intervention has been applied extensively in treating major mental illnesses such as schizophrenia, depression, alcoholism, and anxiety disorders. It consists of a series of in-depth and expert instructional sessions on the phenomenology, etiology, and diagnosis of the disorders. Clinical research findings are explained and made user friendly for the family. Information is also provided about social institutions and systems involved in the care of the patient. Psychoeducational family therapy can be easily combined with other treatment modalities, particularly pharmacotherapy and crisis intervention. The psychodynamic and exploratory psychotherapies are postponed to the later phases of treatment, when the patient and the family are stabilized.

Psychoeducational approaches make extensive use of empirical findings on expressed emotion (EE), communication deviance, affective styles, and problem-solving. This reduces the stressful family processes, recurrence in illness and rehospitalization.

The application of psychoeducational model to childhood depression and suicidality has been particularly productive. The model has been applied preventively to a range of stressful and potentially pathogenic situations for the children such as pediatric cancer, death, and dying. A model for prevention of depression in children of depressed parents has been empirically tested by Beardslee and Schwoeri (18) in the past decade with positive outcomes.

THE FAMILY LIFE CYCLE

The term *family life cycle* proposes that the family moves through a series of developmental stages. Carter and McGoldrick defined critical emotional issues for the family at different stages of the life cycle (19). Haley (8) applied the family life-cycle concept to understanding the clinical problems of families by relating their dysfunctions to the difficulties they have in moving from one developmental stage to another.

Marriage is considered the first stage of the family life cycle (20). The expectable

seven stages of the family life cycle are (1) beginning family, (2) childbearing family, (3) family with school age children, (4) family with teenagers, (5) family as a launching center, (6) family in its middle years, and (7) aging family. Combrinck-Graham (21) proposed the family life spiral, with overlapping development issues for different generations.

FAMILY THERAPY WITH CHILDREN AND ADOLESCENTS: OVERVIEW

The conceptional and technical differences between the fields of child psychiatry and family therapy can be summarized in the following way. Child psychiatrists have accused systemic family therapists of lack of appreciation for the individual child's unique developmental characteristics and intrapsychic life (22,23). According to child psychiatrists, family therapists were oblivious to biologic vulnerabilities and pharmacotherapy. Conversely, family therapists have accused child psychiatrists of lacking understanding of the interpersonal dimensions of the child's life, the multiple sources of stress in contemporary family life, and preoccupation with minute developmental deviations and past events at the expense of present-life realities.

In the 1980s, the two camps approached reconciliation. Recognition of family therapy's limitations with certain populations forced many family therapists to reach "beyond family therapy" and address peer group, psychological (intrapsychic and cognitive), and social dimensions of behavior disorders. Teaching family therapy has been a requirement in child and adolescent, as well as general, psychiatric residency programs for the past 20 years. The integrative approach in treating major mental illnesses has resulted in the consolidation of a true field of family psychiatry (10,24). Psychodynamic and object relations family therapies have demonstrated the many advantages of recognizing the interrelationships between interpersonal and intrapsychic processes (25–27).

We briefly summarize the application of family therapy to multiple disorders of children and adolescents and refer the reader to the references listed for more information.

THEORETICAL CONCEPTS

All schools of family therapy are founded on theoretical concepts that are specifically applicable to family therapy with children and adolescents. In enmeshed families, there is not sufficient distance and objectivity among family members to allow differentiation of the children through the separation and individuation processes. The children have significant difficulties in school and social relationships, further curtailing their maturity. Overinvolvement between a child and

a parent, projective family mechanisms, and triangulation as described by Bowen are major impediments to differentiation and maturity, which can transfer across generations.
